In a monitored patient for whom all first-line neurosurgical options have been exhausted, medical management of elevated ICP is best performed according to an algorithm that emphasizes the logical stepwise application of various interventions (Table 111.3). In addition to the avoidance of hypotension and hypoxia, fluid resuscitation with isotonic crystalloids, seizure prophylaxis and fever control, and head elevation to 30° lowers ICP by reducing jugular venous pressure and should be performed as a general measure in all patients (Table 111.4). Subsequent pharmacologic treatment of brain edema resulting in increased ICP should then progress through the three treatment tiers outlined in Table 111.3. In this algorithm, sedation is the fundamental first step to controlling ICP after rescue neurosurgical intervention has been performed. Sedation lowers thoracic and jugular venous pressure and can calm arterial hypertension and autonomic instability. CPP, calculated as mean arterial pressure minus ICP, can aggravate intracranial hypertension when it is either extremely low or extremely high (Fig. 111.4). Osmotherapy in the form of 0.5 to 1.5 g/kg of 20% mannitol or 23.4% hypertonic saline solution is the mainstay intervention for reducing ICP in critical "brain code" situations. Mannitol should be hung wide open, and 30 mL of 23.4% saline should be pushed through a central venous line slowly over 5 minutes. Doses can be repeated as often as every 30 minutes as needed. Hyperventilation often does not have a sustained effect and should be administered in bursts, typically in tandem with bolus osmotherapy in response to ICP crisis. When intracranial hypertension is associated with systemic acidosis, boluses of 8.4% sodium bicarbonate (50 mEq in 50 ml) or trometanol (THAM, 0.3 mol/L in 500 ml) can reduce ICP and normalize pH.

TABLE 111.3 Stepwise Management Protocol for Intracranial Pressure Crisis (>20 mm Hg for >10 min) in a Monitored Patient[a]

Tier 1
• **Early neurosurgical intervention** including ventricular drainage or craniotomy
• **Sedate** to attain a motionless, quiet state with fentanyl and propofol.
• **Optimize cerebral perfusion pressure** (generally 60-100 mm Hg) to minimize excessive vasodilation from low hypotension or perfusion pressure breakthrough.
Tier 2
• **Bolus osmotherapy** with mannitol 0.5-1.5 g/kg IV or 30 mL 23.4% hypertonic saline repeated up to every 30 min as needed.
• **Hyperventilation** to P_{CO_2} levels of 30-34 mm Hg
• **Paralyze** with a neuromuscular blocking agent such as rocuronium 0.5-1.0 mg/kg/h.
Tier 3
• **Pentobarbital infusion** titrated to ICP <25 mm Hg and EEG burst suppression (1.0-4.0 mg/kg/h)
• **Hypothermia** to a target core temperature of 33°C-35°C
• **Decompressive hemicraniectomy**

Abbreviations: EEG, electroencephalogram; ICP, intracranial pressure; IV, intravenous.
[a]See text for details.

Advanced Treatment Options for Medically Refractory Intracranial Pressure

As outlined in Figure 111.5, escalation beyond the first line of medical interventions for refractory ICP becomes more nuanced and should be tailored to the specific clinical situation and available resources and expertise. These advanced interventions for super-refractory ICP crisis are extensions of each step of first-line intervention. Decompressive hemicraniectomy should be reconsidered. CPP can be further optimized with invasive brain multimodality monitoring with the intention of normalizing CBF or brain tissue oxygen tension (see Chapter 34). After a patient is sedated with conventional agents such as propofol, paralysis or barbiturate anesthesia with pentobarbital can be considered. Bolus osmotherapy can be escalated with continued good effect on ICP to serum osmolality levels far above 320 mOsm/L. When brain hyperemia is considered an important contributing factor, aggressive hyperventilation to P_{CO_2} levels far below 30 mm Hg can be safely attained with concurrent monitoring of brain tissue oxygen tension, CBF, or jugular venous oxygen saturation (normally 70%-90%). Finally, therapeutic temperature modulation can be pushed to beyond simple fever control to lower temperature targets ranging from 35°C to 36°C.

Salvage Interventions for Super-Refractory Intracranial Pressure

Super-refractory ICP refers to the uncommon scenario when ongoing tier 2 intervention involving CPP optimization, repeated doses of bolus osmotherapy, sustained mild hyperventilation, and sedation and paralysis cannot control ICP. The process usually plays out over hours or days. At this point, consideration should be given to proceeding with decompressive hemicraniectomy. If this is not feasible or desired, the two final remaining medical options are to cool to a target temperature of 32°C to 34°C or to induce pentobarbital coma.

TABLE 111.4 Baseline Treatment Measures for Patients at Risk for Intracranial Pressure

• Avoid hypotension and hypoxia.
• Administer only isotonic fluids (avoid all sources of free water).
• Head elevation to 30°
• Control fever.
• Consider seizure prophylaxis.

Decompressive Craniectomy

The ultimate and most effective step to take when confronted with super-refractory ICP is to decompress the cranial vault. Decompression of the cranium allows the brain to swell out of the skull defect and when done properly will definitively control ICP. In severe TBI patients who have suffered ICP >25 mm Hg for 12 to 24 hours despite tier 1 and 2 therapy, craniectomy compared to continued medical therapy with escalation to pentobarbital reduces mortality from 49% to 27% LEVEL 2.[7] Decompressive craniectomy should only be used as a salvage intervention, however, because there is evidence that when performed too early, the procedure may do harm. Another trial that randomized TBI patients to surgery at the very first sign of ICP elevation resulted in increased disability, with no effect on mortality LEVEL 2.[8]

Therapeutic Hypothermia

Lowering body temperature to 33°C to 36°C can reduce ICP elevations that are refractory to standard tier 2 interventions. In general, this technique should be applied by experienced intensivists, and a detailed management protocol is required (see Chapter 38). Advanced feedback-controlled cooling technology using a surface cooling system or endovascular heat exchange catheter is generally required. Target temperature should be titrated to a level that controls ICP but no further, to minimize complications. After cooling for 24 to 72 hours, rewarming at a rate of 0.20°C to 0.33°C per hour can commence. Complications of hypothermia include cardiovascular depression and bradycardia, immunosuppression, impaired coagulation, shivering, and a variety of other metabolic derangements including hypokalemia and hyperglycemia. These complications may explain why mortality was increased in a clinical trial evaluating the use of hypothermia instituted early in the course of ICP elevation after TBI LEVEL 1.[9]

Pentobarbital Coma

High-dose barbiturate therapy, given in doses equivalent to those inducing general anesthesia, is the oldest treatment for super-refractory ICP. A lipid-soluble agent with a half life of 15 to 50 hours, which increases with the duration of infusion, pentobarbital reduces ICP due to a reduction in cerebral blood volume that is coupled to profound reductions in flow and metabolism. Complications include hypotension and cardiovascular depression, critical illness myopathy, and immunosuppression. The loading dose is 5 to 20 mg/kg/h, followed by a maintenance infusion of 1 to 4 mg/kg/h.

Specific Treatments for Brain Edema

Glucocorticoids

Glucocorticoids dramatically and rapidly (in hours) begin to reduce the focal and general signs of brain edema around tumors and abscesses but are not effective for treating the edema that results from cerebral infarction, ICH, SAH, or TBI. The major

FIGURE 111.4 Cerebral autoregulation curve *(blue line)* and relationship between cerebral perfusion pressure (CPP) and intracranial pressure (ICP) in states of abnormal intracranial compliance *(red line)*. Under normal circumstances, cerebral blood flow is held constant across a wide range of CPP (50-150 mm Hg), and changes in vessel caliber have no effect on ICP. In disease states with reduced intracranial compliance, ICP can become elevated when CPP is low due to autoregulatory vasodilation and increased cerebral blood volume (vasodilatory cascade physiology) or when CPP is too high due to passive increases in cerebral blood volume due to increased hydrostatic pressure and hyperemia (autoregulation breakthrough physiology).

mechanism explaining the usefulness in vasogenic brain edema is a direct normalizing effect on endothelial cell function and permeability when the process is triggered by local release of cytokines, angiogenic factors, vascular adhesion molecules, and other inflammatory mediators.

Long-acting, high-potency glucocorticoids are most widely used for the treatment of vasogenic edema related to tumor or infection. The usual dosage of dexamethasone is a starting dose of 10 mg followed by 4 to 6 mg administered 4 times a day thereafter—a dose equivalent in potency to more than 400 mg of cortisol daily. These large doses are about 20 times the normal rate of human endogenous cortisol production. There are no convincing data, clinical or experimental, that glucocorticoids have beneficial effects for the treatment of cytotoxic or osmotic cellular edema regardless of cause. Steroids are also commonly used by neurosurgeons to enhance brain compliance and relaxation during craniotomy despite little evidence of its effectiveness. Steroids may be useful in the management of less common conditions characterized by an inflammatory CSF and brain edema, such as postinfectious acute disseminated encephalomyelitis, central nervous system vasculitis, and meningeal sarcoidosis.

FIGURE 111.5 Stepwise intracranial pressure (ICP) management protocol. Escalation of ICP therapy should advance through first-line interventions to ensure that vital steps are not skipped. The need for repeated bolus osmotherapy, burst hyperventilation, or induction of hypothermia defines ICP crisis. At the level of super-refractory ICP crisis, second-line interventions can be added based on the clinical situation and available resources and expertise. Abbreviations: CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; MMM, multimodality monitoring; OSM, osmolality (mOsms/L); RASS, Richmond Agitation Sedation Scale; THAM, trometamol.

Mannitol

IV mannitol is the most widely used solute for the treatment of intracranial hypertension associated with brain edema. Given in a 20% solution at a dose of 0.25 to 1.5 g/kg, mannitol dehydrates brain tissue and mediates an ICP-lowering effect through several mechanisms. First, it is an osmotic diuretic that creates a concentration gradient across the blood-brain barrier and pulls free water from the brain. This decreases volume of the brain parenchyma and lowers ICP. Second, mannitol increases CPP through plasma expansion and promotes vasoconstriction and cerebral blood volume reduction by decreasing blood viscosity and improving CBF. Finally, mannitol is excreted in the urine resulting in a net clearance of free water and increased serum osmolality.

When given as a bolus infusion, mannitol can lower ICP within as little as 10 to 30 minutes. Dosing may be repeated as frequently as once an hour when ICP is elevated. As opposed to hypertonic saline, mannitol is the preferred treatment for ICP in patients with fluid overload or left ventricular failure. Complications of mannitol therapy include dehydration, electrolyte depletion, and osmotically mediated renal failure. A widened gap of more than 10 mOsm/L between the measured and calculated osmolality may indicate incomplete mannitol clearance by the kidneys and an increased risk of renal tubular necrosis. With repeated bolus dosing a "rebound effect" with successive increases in ICP may occur. Although it is sometimes stated that mannitol loses its efficacy when serum osmolality exceeds 320 mOsm/L, there is scant evidence to support this contention.

Hypertonic Saline

Hypertonic saline has an osmotic effect on the brain because of its high tonicity and ability to effectively remain outside the blood-brain barrier. Numerous animal studies have suggested that fluid resuscitation with hypertonic saline after hemorrhagic shock prevents the ICP increase that follows resuscitation with isotonic fluids. As opposed to mannitol, hypertonic saline is the treatment of choice for increased ICP in patients with hypotension or hypovolemia because it expands intravascular volume. Hypertonic saline solutions may have favorable effects on CBF by producing a boost in CPP and via local effects on the cerebral microvasculature. A clinical trial comparing hypertonic saline with isotonic crystalloid for TBI patients, however, failed to show any benefit. Infusion of a bolus dose of 3%, 7%, 10%, or 23% hypertonic saline solution results in maximal ICP reduction between 30 and 120 minutes accompanied by a surge in CPP. In the United States, use of 30-mL "bullets" of 23.4% saline has become the most popular form of hypertonic saline bolus osmotherapy. Common complications of hypertonic saline administration include volume overload, pulmonary edema, and electrolyte depletion.

IDIOPATHIC INTRACRANIAL HYPERTENSION

Idiopathic intracranial hypertension (IIH) describes a heterogeneous group of disorders characterized by increased ICP when intracranial mass lesions, obstructive hydrocephalus, intracranial infection, and hypertensive encephalopathy have been excluded. IIH is also termed *pseudotumor cerebri*. The best documented risk factors for IIH are obesity, hypervitaminosis A, steroid withdrawal, and female gender. The term *benign* has been used because spontaneous recovery is characteristic, but the condition is far from harmless: Serious threats to vision make accurate diagnosis and therapeutic intervention a necessity.

Causes of Idiopathic Intracranial Hypertension

Endocrine and Metabolic Disorders

IIH is most commonly seen in healthy women with a history of menstrual dysfunction. Frequently, the women are moderately or markedly overweight (without evidence of alveolar hypoventilation). Menstrual irregularity or amenorrhea is common; galactorrhea is an unusual symptom. The histories often emphasize excessive premenstrual weight gain. Endocrine studies have not revealed specific abnormalities of urinary gonadotropins or estrogens, and the pathogenesis is unknown. IIH has a complex relationship to adrenal hormones. Rarely, IIH is a complication of Addison disease or Cushing disease. Improvement occurs after restoration of a normal adrenal state; the mechanism in either circumstance is unknown.

IIH has also occurred in patients treated with corticosteroids for prolonged periods. Many of the patients had allergic skin disorders or asthma during childhood; IIH generally occurs when the steroid dosage is reduced but evidence of hyperadrenalism persisted. Hypoparathyroidism may also present with increased ICP; hypocalcemic seizures or cerebral calcifications may further complicate the clinical picture. IIH has also been reported in women taking oral progestational drugs.

Drugs and Toxins

IIH has been reported in otherwise healthy adolescents who are taking large doses of vitamin A for the treatment of acne. Oral doses as low as 25,000 IU daily may cause headache and papilledema with rapid improvement after cessation of the therapy. The syndrome is said to have occurred in Arctic explorers who consumed polar bear liver, a great source of vitamin A. Some cases of IIH that are manifested by bulging fontanel and papilledema have been reported in children given tetracycline. The mechanisms involved are obscure. Spontaneous, rapid recovery occurs when the drugs are stopped. Amiodarone and lithium carbonate, as well as the insecticide chlordecone, have also been reported to cause IIH.

Hematologic and Connective Tissue Disorders

Papilledema and increased ICP have been attributed to severe iron deficiency anemia with striking improvement after treatment of the anemia. Presumably, the mechanism partly reflects the marked increase in CBF that accompanies profound anemia. IIH has also been observed as a manifestation of systemic lupus erythematosus.

Pulmonary Encephalopathy

IIH may be a major complication of chronic, hypoxic hypercapnia caused by paralytic states such as muscular dystrophy and cervical myelopathy; it may also be a complication of obstructive pulmonary disease and obstructive sleep apnea. There is a chronic increase of CBF because of hypoxia and carbon dioxide retention. Patients usually appear mentally dull and encephalopathic and thus differ from most patients with IIH.

Spinal Cord Diseases

IIH rarely occurs with tumors of the spinal cord or cauda equina or with polyneuritis. Papilledema and headache disappear with treatment of the spinal lesion or regression of the polyneuropathy.

The mechanism may involve the effects of an elevated CSF protein on CSF absorption at the arachnoid villi in both cranial and spinal subarachnoid spaces. Occurrence of this syndrome, however, does not correlate with the degree of protein elevation.

Pathobiology

Several mechanisms have been considered as possible explanations for the pathophysiology of IIH. These include an increased rate of CSF formation, a sustained increase in intracranial venous pressure, a decreased rate of CSF absorption by arachnoid villi apart from venous occlusive disease, and an increase in brain volume caused by an increase in blood volume or extravascular fluid volume simulating a form of brain edema.

No data are available regarding the rate of CSF formation, and the only condition in which increased CSF formation has been demonstrated is choroid plexus papilloma. Increased CSF production might explain the pathophysiology in some of the diverse conditions associated with IIH, but this mechanism remains unproven. A sustained increase in intracranial venous pressure associated with decreased CSF absorption has similarly not been documented in IIH. The currently most favored explanation for IIH is decreased CSF absorption (in the absence of venous occlusion) resulting from altered function of the arachnoid villi. For reasons that are unclear, however, hydrocephalus does not occur in IIH. On the contrary, very often, the brain appears swollen and the ventricles are smaller than normal. It has been hypothesized that IIH might have caused by an increase in brain volume secondary to an increase in extracellular fluid volume. An increase in brain volume would be expected if the extracellular space of the brain were expanded; this is now hypothesized to be the result of impaired perivascular glymphatic drainage of interstitial fluid out of the brain.

Any theory of the pathogenesis of IIH must be consonant with the rapid therapeutic response of IIH to shunting of CSF by an implanted lumbar peritoneal shunt. Impaired CSF absorption or increased CSF formation would explain the occurrence of IIH in most cases; however, the limited data available, currently, do not allow any firm conclusions.

One of the more common forms of IIH appears in otherwise healthy persons in the absence of any of the aforementioned etiologic factors. Both genders are affected, women more than men, and occurrence is most often in patients between 10 and 50 years of age.

Clinical Features

Typically, the first symptoms are headache and impaired vision. The headache may be worse on awakening and aggravated by coughing and straining. It is often mild or may be entirely absent. In some cases, pulse-synchronous tinnitus occurs. The most common ocular complaint is visual blurring, a manifestation of papilledema. Some patients complain of brief, fleeting moments of dimming or complete loss of vision occurring many times during the day, at times accentuated or precipitated by coughing and straining. This ominous symptom indicates that vision is in jeopardy. Visual loss may be minimal despite severe chronic papilledema, including retinal hemorrhages; however, blindness occasionally develops rapidly (ie, <24 h). Visual field testing characteristically shows enlargement of the blind spots and may show constriction of the peripheral fields and central or paracentral scotoma. Diplopia caused by unilateral or bilateral sixth nerve palsy may develop as a result of increased ICP. The neurologic examination is otherwise normal. A major clinical point is that patients with IIH usually look well; their apparent well-being belies the ominous appearance of the papilledema. Although the disorder most often lasts for months, it may persist for years without serious sequelae. Remissions may be followed by one or more recurrences in 5% to 10% of cases. In some patients, IIH may be responsible for development of the *empty sella syndrome*, in which radiographic image showing enlargement of the sella turcica simulates the appearance of a pituitary tumor. CT reveals that the enlarged sella is filled with CSF flowing from a defect of its diaphragm.

Diagnosis

The patient with headache and papilledema without other neurologic signs suggest the diagnosis of IIH. Although the diagnosis of IIH may be suspected by the appearance of well-being and a history of some of the associated etiologic features listed previously, the diagnosis is essentially one of exclusion and depends on ruling out the more common structural causes of increased ICP. Brain tumor, particularly when located in relatively "silent" areas such as the frontal lobes or right temporal lobe or when obstructing the ventricular system, may be manifested only by headache and papilledema. Patients with chronic subdural hematoma, without a history of significant trauma, may have the same symptoms. Other important conditions to exclude include viral meningitis and other central nervous system infections and dural sinus thrombosis.

Diagnostic evaluation depends on MRI with venography and lumbar puncture. Lumbar puncture should be deferred until imaging indicates that the perimesencephalic cisterns are open. MRI shows no distinct pathology other than a variety of subtle findings that occur as the result of chronically increased ICP (Table 111.5). Diagnostic lumbar puncture is mandatory to establish the diagnosis of IIH. In obesity, the normal upper limit of CSF pressure is 250 mm Hg. In IIH, the CSF pressure is elevated, usually between 250 and 600 mm Hg, but the fluid is otherwise normal. The protein content is often in the lower range of normal, and lumbar CSF protein levels of 10 to 20 mg/dL are common. CSF protein content greater than 50 mg/dL, decreased CSF glucose, or increased cell count throws doubt on the diagnosis of IIH and suggests other disease conditions.

Pseudopapilledema may be a source of diagnostic confusion. In this developmental anomaly of the fundus, the ophthalmic appearance may be indistinguishable from true

TABLE 111.5 Typical Neuroimaging Features Found in Idiopathic Intracranial Hypertension

• Swollen brain
• Slit-like ventricles
• Empty sella
• Increased tortuosity of optic nerve
• Enlarged optic nerve sheath (perioptic subarachnoid space)
• Flattened posterior globe
• Intraocular protrusion of optic nerve head
• Attenuation or stenosis of the cerebrovenous sinuses

papilledema; there is elevation of the optic disc, although exudates and hemorrhages are absent. Visual acuity is normal, but visual fields may show enlargement of the blind spots. The unchanging appearance of the fundus in subsequent examinations favors the diagnosis of pseudopapilledema, as does the finding of normal CSF pressure on lumbar puncture. Optic neuritis is differentiated from IIH by visual loss and normal CSF pressure.

Treatment

The common form of IIH in patients with menstrual disorders and obesity requires individualized management. This syndrome is self-limited in most cases, and after some weeks or months, spontaneous remissions occur, making evaluation of therapy outcomes difficult. Recurrent episodes have been noted in about 5% to 10% of patients, and the illness seldom lasts for years. In the extremely obese patient (body mass index >30 kg/m^2), weight reduction is recommended. Daily lumbar puncture was used in the past to lower CSF pressure to normal levels by removing sufficient fluid; 15 to 30 mL of fluid may be removed. In many cases, short-term headache relief occurs, but as a rule, it tends to recur quickly. Because the value of serial lumbar punctures is dubious, this approach is no longer recommended LEVEL 3.[10]

An algorithm for management of established IIH is shown in Figure 111.6. A CSF shunt procedure, such as a lumboperitoneal shunt, is useful in patients with intractable headache and progressive visual impairment. It may dramatically relieve symptoms. Optic nerve sheath fenestration has its advocates as the procedure of choice to preserve vision.

Acetazolamide 500 mg 2 to 4 times a day has been used because this carbonic anhydrase inhibitor reduces CSF formation. The Neuro-Ophthalmology Research Disease Investigator Consortium trial has demonstrated that acetazolamide 1,000 mg titrated upward, along with a salt restriction and weight reduction diet, results in modest improvement in visual field function and improved quality of life in patients with mild pseudotumor cerebri LEVEL 1.[11,12] Topiramate, 25 to 50 mg twice a day, a carbonic anhydrase inhibitor and appetite suppressant as well, can be used as an alternative to acetazolamide. Hypertonic IV solutions (20% mannitol) to lower ICP may be used in acute situations when there is rapidly failing vision and surgical intervention is awaited. When the pseudotumor syndrome is a manifestation of

112 Spontaneous Intracranial Hypotension

Kevin E. Immanuel, Tiffany R. Chang, and Kiwon Lee

KEY POINTS

1. Intracranial hypotension symptoms are not restricted to postural headaches and can have more severe presentation including coma.
2. Epidural blood patch is a mainstay management for cerebrospinal leaks that could not resolve with conservative management.
3. Brain sagging should be considered in the setting of an acute deterioration in postcraniotomy patient population.

INTRODUCTION

In 1825, Magendie described a patient with symptoms of unsteadiness and vertigo resulting from hypotension of spinal fluid and ventricular collapse. A century later in 1938, Georg Schaltenbrand described a condition, which he termed *spontaneous or essential aliquorrhea*, that was marked by postural headache and low cerebrospinal fluid (CSF) pressure.

Intracranial hypotension is a condition that occurs as a result of loss of CSF volume. The loss of CSF can occur at different location of the neural axis depending on the underlying etiology. For example, CSF leaks can occur at a skull base fracture from trauma and postdural puncture CSF leaks can occur at the spinal level of needle insertion. A similar syndrome of intracranial hypotension can also be seen in patients with excessive CSF drainage by ventriculoperitoneal shunts and postcraniotomy (ie, brain sagging).

SPONTANEOUS INTRACRANIAL HYPOTENSION

Spontaneous intracranial hypotension (SIH) is the result of an idiopathic CSF leak. It is an increasingly more recognized etiology of intracranial hypotension. The SIH should be part of the differential diagnosis for any new-onset, persistent daily headache with orthostatic quality.

Epidemiology

The estimated annual incidence is 5 cases per 100,000 with an estimated prevalence of 1 case per 50,000. It is reported more in women than in men in a 2:1 ratio. Symptoms typically begin in the fourth to fifth decade of life; however, it has been reported in all age groups including in children.

Pathobiology

Most spontaneous CSF leaks occur at the cervicothoracic junction or thoracic spine; however, the underlying mechanism is not clearly defined. Some proposed mechanisms include spontaneous rupture of an arachnoid membrane and a variety of dura abnormalities such as meningeal diverticula, perineural (Tarlov) cyst, and localized absence of dura as well as spontaneous dura tears occurring where the spinal roots leave the subarachnoid space. In case reports, some spontaneous leaks have been attributed to underlying connective tissue disorders such as Marfan syndrome and Ehlers-Danlos syndrome (type II). Other predisposing etiologies include autosomal dominant polycystic kidney disease, Lehman syndrome, and neurofibromatosis type 1.

Clinical Features

Presenting symptoms are often not localized to the site of the leak and manifest in a variety of ways, making this diagnosis challenging. The symptoms are thought to be the result of loss of CSF buoyancy due to low CSF volume, resulting in downward displacement of the brain, causing traction on pain-sensitive structures such as the meninges, some cranial nerves, or compensatory engorgement of pain-sensitive intracranial venous structures, particularly in upright position.

The most common initial presentation is a new-onset, persistent daily headache with an orthostatic quality. It is usually described as a throbbing or pressure-like headache but can also be dull. The location is often holocephalic but may be localized to the frontal or occipital region. The headache is similar to postdural puncture headache, but the postural component may not be as dramatic depending on rate and volume of CSF loss. The onset of headache in SIH is minutes to hours compared to seconds as in postdural puncture headaches. The headache is alleviated by lying flat for about 15 to 30 minutes, but resolution can be delayed or incomplete. If unmanaged, SIH can lead to a chronic daily headache that may not be orthostatic or relieved by recumbency. It is important to elicit the orthostatic nature of the headache at the initial onset, as this feature may become less obvious to the patient as the headache becomes chronic.

Additional symptoms reported include visual changes, diplopia, hearing changes, neck pain and/or stiffness, convulsions, nausea, and vomiting. Atypical presentations include parkinsonism, dementia, hypopituitarism, seizures, and coma. Spinal symptoms including radicular symptoms and quadriparesis are rare. Symptoms are typically reversible with normalization of CSF pressure. The onset and exacerbation of symptoms can be associated with coughing, laughing, Valsalva maneuver, and post coitus.

TABLE 112.1 Diagnostic Criteria for Headache Attributed to Low Cerebrospinal Fluid (CSF) Pressure as Defined in International Classification of Headache Disorders, 3rd Edition (ICHD-3)[a]

A	Any new-onset, often orthostatic,[b] headache that fulfills criteria C
B	Either or both of the following: • Low CSF opening pressure (<6 cm H_2O) • Evidence of CSF leakage on imaging
C	Headache has developed in temporal relation to the low CSF pressure or CSF leakage or has led to its discovery
D	Not better accounted for by another ICHD-3 diagnosis

[b]Orthostatic relationship characterized by worsening in upright position and improvement in horizontal position is not relied on as a diagnostic criteria.

Diagnosis

An SIH is part of the differential diagnosis for headaches caused by intracranial hypotension. The diagnostic criteria for any headaches related to intracranial hypotension are defined in the International Classification of Headache Disorders, 3rd edition, as noted in **Table 112.1**. The diagnostic criteria for SIH are also defined in International Classification of Headache Disorders, 3rd edition, and noted in **Table 112.2**. A diagnosis of SIH cannot be made if patient had a dural puncture or another known mechanism of dural injury within a month of onset of headache.

In addition to history and physical examination, use of magnetic resonance imaging (MRI) of the brain, particularly T1-weighted images postgadolinium injection, is very helpful in making the diagnosis (Fig. 112.1). Five characteristic features seen on postgadolinium-enhanced MRI of the brain are subdural fluid collections, diffuse enhancement of pachymeninges, engorgement of venous structures, pituitary hyperemia, and sagging of the brain, which make up the mnemonic *SEEPS* (**Table 112.3**). Most observed MRI of the brain findings are a result of a compensatory change due to the loss of CSF volume. Based on the Monroe-Kellie principle, a decrease in CSF volume will result in brain sag and compensatory venous engorgement.

TABLE 112.2 Diagnostic Criteria for Headache Attributed to Spontaneous Intracranial Hypotension as Defined in International Classification of Headache Disorders, 3rd Edition (ICHD-3)[a]

A	Any new-onset headache that fulfills criteria in **Table 112.1**
B	Absence of a procedure (for at least a month) or trauma known to be able to cause CSF leakage
C	Headache has developed in temporal relation to the low CSF pressure or CSF leakage, or has led to its discovery
D	Not better accounted for by another ICHD-3 diagnosis

Abbreviation: CSF, cerebrospinal fluid.
[a]From Headache Classification Committee of the International Headache Society. The International Classification of Headache Disorders, 3rd edition. *Cephalalgia*. 2018;38(1):102-104.

There are several case reports that demonstrate improvement in MRI findings after successful treatment of CSF leak. It is important to note that in about 20% of patients diagnosed with SIH, the MRI findings will be normal; therefore, a normal MRI does not exclude the diagnosis of SIH.

Lumbar puncture (LP) can be performed to obtain opening CSF pressure. It is typically employed if there is a high suspicion of SIH, although MRI findings are normal. The LP should be performed after MRI of the brain is obtained to avoid post-LP MRI pachymeningeal enhancement, which can confound the diagnosis. A CSF opening pressure of less than 6 cm H_2O is a diagnostic criterion for SIH but not a requirement (see **Table 112.1**). In approximately 25% of patients with SIH, the CSF opening pressure is normal. In addition to low CSF opening pressure, lymphocytic pleocytosis as well as elevated protein concentration and xanthochromia have been reported.

If the MRI and CSF findings are inconclusive despite having high suspicion of SIH, computed tomographic (CT) myelography with iodinated contrast or magnetic resonance (MR) myelography with gadolinium of the spine as well as radionucleotide cisternography is advocated. Likewise, if initial treatment is ineffective and localization of the CSF leaks is desired for direct surgical intervention, these imaging modalities can accurately define the location and extent of CSF leak. The CT myelography is the most accurate study for localization of CSF leak. It can also reveal the underlying etiology of the leak, such as meningeal diverticula. It is recommended that early and delayed cuts are obtained at each spinal level to detect both fast and slow CSF leaks. The MR myelography with intrathecal gadolinium and noninvasive MR myelography have been used increasingly as a reasonable alternative. Although historically, radionucleotide cisternography has been used as an indirect indicator of CSF leak, it is seldom employed when CT or MR myelography is available, as it is less sensitive. However, simultaneous use of CT and single-photon emission computed tomography has improved the sensitivity of radionucleotide cisternography detecting the exact location of CSF leak.

Although findings from CT of the brain are not as conclusive as MRI findings, it is useful when MRI is unavailable. Nontraumatic subdural fluid collections, ventricular collapse, obliteration of subarachnoid cisterns, and displacement of pons and cerebellar tonsils below the foramen magnum all contribute to making the diagnosis (see Fig. 112.1A).

The MRI of the spine may demonstrate spinal manifestations of intracranial hypotension; however, it is not always useful in localizing the site of the CSF leak. Some imaging findings on MRI of the spine include dural enhancement, meningeal diverticula, dilated epidural or intradural veins, syringomyelia, retrospinal C1-C2 fluid, and extrathecal CSF collections. Use of MRI of the spine may be indicated if patient has neuropathic or myelopathic symptoms.

Sagging of the brain

Management

General Management

Most cases of SIH are self-limited, although the time course for resolution is variable. Thus, the initial treatment is usually conservative medical management with bed rest in a recumbent position, adequate oral hydration, oral or intravenous caffeine, and use of abdominal binders. Caffeine has been used to serve as a vasoconstrictor to mitigate symptoms that are attributable to compensatory venous engorgement.

For patients who do not benefit from conservative medical management and continue to have persistent and debilitating symptoms, the mainstay reported treatment is the use of epidural blood patch (EBP). It involves injection of about 10 to 20 mL of autologous blood into the spinal epidural space. It can be injected directly at the level of CSF leak if known or can be placed in the safer lower lumbar region (**Fig. 112.2**). The patient is usually placed in Trendelenburg position for up to 60 minutes after injection. The proposed mechanism is twofold: first to replace the lost CSF volume with blood volume in the spinal canal and second to serve as a sealant for any dural defect. Although there are no randomized controlled trials to evaluate the effectiveness of EBP use, it is reported to improve symptoms in 30% to 70% of patients after the first injection. Symptomatic relief is almost immediate but may not provide complete or permanent resolution of symptoms. Two or more EBPs may be required to achieve sustained relief. Thirty percent to 50% of patients may benefit from multiple administrations of EBP. After the initial one, subsequent EBP may be done with much larger volume of blood (up to 100-150 mL). It is expected that symptomatic relief should be sustained for at least a few days. Complications from EBP are rare, but they include neck and back pain, worsening of headache due to dural puncture, meningeal irritation, and rebound intracranial hypertension.

If the exact site of CSF leak is known from imaging studies and EBP does not provide sustained relief, use of percutaneous placement of fibrin sealant or directed EBP is advised. In refractory cases where the symptoms are debilitating and the site of leak is known, surgical repair using suture, aneurysm clip, muscle pledget with fibrin sealant, and Gelfoam may be considered.

Outcomes

As previously stated, symptoms of SIH are often self-limited; however, timing of resolution of symptoms varies even after CSF leakage is resolved. Important complications of spontaneous CSF leaks include subdural hematoma, bibrachial amyotrophy, cerebral venous thrombosis, and, rarely, superficial siderosis. Rare but more severe complications have been reported in case reports including mental status decline, coma, and vascular infarcts from transtentorial and downward cerebellar herniation.

POSTCRANIOTOMY BRAIN SAGGING

"Brain sagging" or "sinking brain syndrome" is a serious postoperative complication. It should be part of the differential diagnosis for any patient who clinically declines after craniotomy.

Clinical Features

The syndrome typically develops as an immediate postoperative finding, or within 48 hours of surgery, often once sedation is stopped. The hallmark presentation is anisocoria with acute mental status decline. Early recognition is paramount to avoid irreversible transtentorial herniation leading to permanent damage. Reported risk factors include presurgical presence of global cerebral edema, intraoperative lumbar drain, ventriculostomy, and prolonged surgery.

TABLE 112.4 Criteria for Postcraniotomy "Brain Sagging" Syndrome

- Clinical signs of transtentorial herniation (eg, reduced level of consciousness, motor posturing, pupillary and oculomotor abnormalities)
- Radiographic signs of excess intracranial air and effacement of the basal cisterns
- Improvement of symptoms in Trendelenburg (head down) position

Diagnosis

Brain sagging may be diagnosed with three classic criteria: (1) clinical signs of transtentorial herniation, (2) excessive intracranial air with effacement of the basal cisterns (often with an oblong brain stem), and (3) improvement of symptoms when patient is placed in Trendelenburg position (**Table 112.4**).

Neuroimaging, CT or MRI of the brain, may reveal crowding of the posterior fossa as well as flattening of the optic chiasm and anterior pons, descent of the brain stem and cerebellar tonsils, and reduction of subarachnoid cisternal spaces. On imaging, patients may have a significant amount of pneumocephalus and demonstrate Mount Fuji sign, peaking of the frontal lobes with excessive intracranial air (**Fig. 112.3**). Remote hemorrhage, most often cerebellar in location, may also be seen on brain imaging following cranial or spinal surgery. This is attributed to venous bleeding secondary to intraoperative CSF loss. Remote cerebellar hemorrhage may give the appearance of a "zebra sign" on neuroimaging and can be associated with local edema and mass effect (**Fig. 112.4**).

Management

Most patients with brain sagging respond quickly when placed in Trendelenburg position. If after an hour of Trendelenburg

FIGURE 112.3 Pneumocephalus (Mount Fuji sign) after craniotomy for evacuation of subdural hemorrhage.

FIGURE 112.4 Gradient echo magnetic resonance imaging of brain showing bilateral low intensity *(white arrows)* within the cerebellar sulci consistent with chronic hemosiderin staining due to remote cerebellar hemorrhage. This pattern of irregular stripes are alternating blood and cerebellum that is sometimes referred to as the *zebra sign*. (From Paul J, Jhaveri MD, Lewis SL. Teaching neuroimages: remote cerebellar hemorrhage following resection of a supratentorial tumor. *Neurology*. 2011;77[14]:e82-e83.)

position does not improve neurologic condition, one should question the diagnosis and search for other causes of mental status deterioration. An injection of 10 to 15 mL of autologous blood (blood patch) into the lumbar space can resolve persistent symptoms of postural headache and neurologic symptoms (eg, dizziness, lethargy, dysarthria) once the herniation syndrome has been reversed. In extreme cases of brain stem herniation from CSF hypovolemia, controlled infusion of isotonic crystalloid solution via a lumbar catheter has been reported to reverse the syndrome. Conservative management with bed rest, caffeine, oral hydration, and use of an abdominal binder has also been reported as effective in less severe cases.

Intervertebral Disk Disease and Radiculopathy 113

Hani Malone and Peter D. Angevine

KEY POINTS

1. Back pain is ubiquitous, and radiographic evidence of degenerative disk disease is common in adults. Radiculopathy from degenerative disk disease is usually self-limited.
2. Most patients should undergo a 6-week trial of rest, pain control, and physical therapy, prior to ordering magnetic resonance imaging and referral to a surgical specialist.
3. A more urgent referral should be initiated in the presence of symptoms of cauda equina syndrome, myelopathy, or acute/progressive motor weakness.
4. Surgical treatment should be reserved for those cases in which conservative management has failed and disk disease identified on neuroimaging correlates with clinical presentation.

INTRODUCTION

Intervertebral disk disease is responsible for a range of pain syndromes that have been recognized since the time of Hippocrates. The first reported treatment of intervertebral disk pathology occurred in 1909, when Krause operated on a patient who had been diagnosed by Oppenheimer as suffering from a lesion localized to the L4 root. In surgery, Krause found an extradural mass that was described pathologically as a chondroma and the operation to remove it apparently affected a cure. In 1934, Mixter and Barr were the first to point out that these lesions were actually fragments of intervertebral disks and that they were responsible for radicular pain. They further proved the efficacy of surgical treatment in their series of 58 patients treated with laminectomy and diskectomy for lumbar disk herniation.

EPIDEMIOLOGY

In the United States, back pain is the most common reason for limiting physical activity in people younger than 45 years; it is the second most frequent cause of visits to a physician, the fifth cause of hospital admissions, and the third leading cause of surgery. In many countries, it is the most common cause of absenteeism from work, accounting for more than 12% of sick days. The aggregate economic cost in the Netherlands in 1991 was estimated to be 1.7% of gross national product. This figure likely represents the typical cost incurred by developed nations. In the United States, the aggregate cost of lower back pain is estimated to exceed $100 billion per year.

According to Andersson, "Chronic low back pain has become a diagnosis of convenience for many people who are actually disabled for socioeconomic, work-related, or psychological reasons." The complexity of the problem is measured in a lengthy literature and a long list of approaches to therapy. Medications and other therapies include nonsteroidal anti-inflammatory drugs, opiates, and antidepressants; extradural injection of steroids; decompressive surgery; physical therapy, including massage and exercise; chiropractic treatment; and acupuncture. In Finland, a third of the direct costs were spent on complementary therapies. Multidisciplinary spine centers and pain centers may be sources of the most effective approach to management.

Pathologic studies have demonstrated that almost all individuals older than the age of 30 years have some evidence of disk degeneration. As individuals age, spondylosis and osteochondrosis, the long-term sequelae of degenerative disk disease, become more and more prominent. Intervertebral disk rupture is most common in the fourth to sixth decades of life. It is relatively rare before the age of 25 years and is less common after the age of 60 years. Importantly, pathologic or radiographic findings consistent with disk disease are often asymptomatic and clinically insignificant. Although some maintain that degenerative disk disease is a byproduct of the modern human environment, there is no conclusive evidence that back pain has significantly increased over the past 50 years. Fortunately, the efficacy and morbidity associated with treating intervertebral disk disease has improved considerably.

PATHOPHYSIOLOGY

Intervertebral Disk Disease

Displaced disk material may cause signs and symptoms by bulging or protruding beneath an attenuated annulus fibrosus, or the material may extrude through a tear in the annulus and project directly into the spinal canal (**Fig. 113.1**). In either case, the encroaching disk material may irritate or compress nerve roots as they approach their exit through the neural foramina. In cervical and thoracic regions, the problem is more neurologically complex because the spinal cord itself, as well as the adjacent nerve roots, may be involved. At cervical and thoracic levels, signs and symptoms are caused either by cord compression or by a combination of cord and nerve root compression. In the lumbar region, signs and symptoms solely relate to the compression

FIGURE 113.1 Anatomic illustration of the spinal canal and intervertebral disk. **A:** Demonstrating normal anatomy of the lumbar spine. **B:** An annular "disk bulge." **C:** An annular tear with herniation of the nucleus pulposus causing nerve root impingement.

of nerve roots or to compression of the cauda equina if the disk is large enough to crowd the entire spinal canal.

There are eight spinal nerve roots in the cervical spine (C1-C8), which are numbered according to vertebra below the corresponding disk space. For example, the C4 nerve root exits through the neural foramen at the C3-C4 level and the C5 nerve root exits via the C4-C5 foramen. The C8 nerve root courses through the C7-T1 intervertebral foramen, as there is no C8 vertebra. Conversely, nerve roots in the thoracic and lumbar spine are numbered according to the vertebrae above their exit through the intervertebral foramen. For example, the L5 nerve root exits the spinal canal at the level of L5-S1.

Importantly, paramedian lumbar disk herniations generally impinge on nerve roots that exit the spinal canal, a level below the site of disk herniation. For example, a paramedian herniated disk at the L4-L5 level compresses the L5 nerve root, which exits the spinal canal through the L5-S1 intervertebral foramen. This is not the case for *far lateral* disk herniations, which extend laterally to compress the rostral lumbar nerve root at the affected level. A far lateral L3-L4 lumbar disk herniation, for example, may compress the L3 nerve root either within the foramen or more distally as the root passes over the disk space (Fig. 113.2). Far lateral disk herniations account for 10% of all lumbar disk herniations, affect higher lumbar levels, and are likely to cause objective neurologic deficit. A far lateral disk herniation should be suspected with acute onset of an isolated upper lumbar radiculopathy that affects L2, L3, or L4.

In the cervical spine, degenerative disk disease most commonly affects the C5-C6 and C6-C7 levels. In the lumbar spine, most disk degeneration occurs at the L4-L5 and L5-S1 levels. This pattern suggests that the dynamics of pathologic change are partly related to wear and tear and to the repetitive trauma of motion.

FIGURE 113.2 Far lateral disk herniation. **A:** Two sites of possible upper nerve root compression from a far lateral disk herniation. Root compression may occur at the level of the disk space (*1*) or from a rostrally migrated fragment into the foramen of the upper nerve root (*2*). **B:** Magnetic resonance imaging demonstrates a left far lateral disk herniation at the L3-L4 level (*arrow*).

TABLE 113.1 Common Root Syndromes of Intervertebral Disk Disease

Disk space	L3-L4	L4-L5	L5-S1	C4-C5	C5-C6	C6-C7	C7-T1
Root affected	L4	L5	S1	C5	C6	C7	C8
Muscles affected	Quadriceps	Peroneals, anterior tibial, extensor hallucis longus	Gluteus maximus, gastrocnemius, plantar flexors of toes	Deltoid, biceps	Biceps	Triceps, wrist extensors	Intrinsic hand muscles
Area of pain and sensory loss	Anterior thigh, medial shin	Great toe, dorsum of foot	Lateral foot, small toe	Shoulder, anterior arm	Radial forearm	Thumb, middle fingers	Index, fourth, and fifth fingers
Reflex affected	Knee jerk	Posterior tibial	Ankle jerk	Biceps	Biceps	Triceps	Triceps
Straight leg raising	Many do not increase pain	Aggravates root pain	Aggravates root pain	—	—	—	—

Thoracic disk protrusions, except at the lower thoracic levels, differ from cervical and lumbar disorders in both genesis and histopathology. Motion does not play a significant role, as thoracic vertebrae are designed for stability rather than motion, and the heavy rib cage contributes to the rigidity of this region. Ruptured thoracic disks are markedly different on gross and microscopic examination, and their consistency seldom resembles that of cervical and lumbar ruptured disks. These pathologic differences suggest a separate mechanism of injury in thoracic disk disease. Trauma has been accepted as a prime cause of thoracic disk herniation, but genetic predisposition also likely plays a role. Trauma may aggravate this susceptibility and ultimately catalyze rupture. Intervertebral disk disease is far less common in the thoracic spine compared to lumbar and cervical segments.

The signs and symptoms of herniated disks relate not only to the size and strategic location of the disk fragments but also to the size and configuration of the spinal canal. Congenital spinal stenosis, which is an abnormally narrow spinal canal, is an example of an inherited anomaly that influences the clinical impact of disk disease. Degenerative spondylosis leads to spinal stenosis and narrowing of the neural foramina through osteophyte formation and hypertrophy of the ligamentum flavum and facet joints. Degenerative spondylosis and congenital spinal stenosis are major contributors to compression syndromes of the spinal cord and cauda equina, as even small disk protrusions in these patients can further compromise an already limited canal. In a canal of normal dimensions, the severity of neural compression and the clinical impact of a protruded disk fragment depends more on the site of rupture and the volume of the extruded material.

CLINICAL FEATURES

Radicular Pain and Lumbar Disk Disease

Root syndromes of intervertebral disk disease are often episodic, so remissions are characteristic. The pain may be restricted to the back or follow a radicular distribution in one or both legs. Lumbar pain may increase after heavy lifting or twisting of the spine. It is often relieved when the patient lies down. Some patients, however, are more comfortable sitting, and many find no comfortable position.

Physical examination often reveals loss of lumbar lordosis or flattening of the lumbar spine with splinting and asymmetric prominence of the long erector muscles. Range of motion of the lumbar spine is reduced by the protective splinting of paraspinal muscles, and attempted movement in some planes induces severe back pain. There may be tenderness of the adjacent vertebrae. When the patient is erect, one gluteal fold may hang down and show added skin creases because the gluteus is wasted—evidence of involvement of the S1 root. Passive straight leg raise, when the patient is supine and the examiner lifts the patient's leg while the knee is straight, is reduced in range and increases back and leg pain. Muscle atrophy and weakness or sciatic tenderness and discomfort may occur on direct pressure at some point along the nerve from the sciatic notch to the calf. This is particularly true in older patients.

The typical syndromes of root compression at lumbar levels are described in Table 113.1. Importantly, clinical signs may not be as distinct in actual practice as the table implies. More than 80% of syndromes affect the L5 or S1 nerve roots (Table 113.2). Compression of the nerve root at these levels results in "sciatica," a sharp and burning pain that radiates down the posterior/lateral aspect of the leg to the foot or ankle (Fig. 113.3). When the lesion affects L4 or higher roots, straight leg raise does not stretch the roots above L5. Nerve root compression is often associated with numbness and tingling. Radicular pain resulting from disk disease classically intensifies with Valsalva (coughing, defecating, sneezing).

TABLE 113.2 Signs of Lumbar Disk Herniation in 97 Patients[a,b]

Disk space	L2-L3	L3-L4	L4-L5	L5-S1
Patients (n)	1	9	45	42
Weak muscles				
Anterior tibial, extensor hallucis	0	3	13	3
Gastrocnemius, plantar responses of foot	0	0	2	3
Quadriceps	0	3	0	0
Reflex affected				
Knee jerk	1	6	4	0
Ankle jerk	0	1	12	23

FIGURE 113.3 Magnetic resonance imaging of lumbosacral disk herniation. Sagittal **(A)** and axial **(B)** T2-weighted magnetic resonance imaging demonstrate a large L5-S1 disk herniation on the left side. Clinically, this patient had an S1 radiculopathy that did not respond to conservative therapy. Complete relief of symptoms followed lumbar diskectomy.

Thoracic Disk Rupture

The thoracic spine is designed for rigidity rather than excursion, thus wear and tear from motion and stress may not cause thoracic disk protrusion, and clinical disorders are rare. Thoracic disk disease may result from chronic vertebral changes incident to Scheuermann disease or juvenile osteochondritis with later trauma. The small capacity of the thoracic spinal canal makes this region vulnerable to cord compression from disk herniation (Fig. 113.4A). By the same token, decompressive operations are more precarious and require meticulous care to avoid damaging the spinal cord. Calcific changes are common in pathologic thoracic intervertebral disks (Fig. 113.4B), which pose additional challenges when performing diskectomy. The lower thoracic levels, however, are more capacious, and although the conus medullaris or cauda equina may be damaged by disk protrusions, surgical approaches are less hazardous compared to higher levels.

FIGURE 113.4 Calcified thoracic disk herniation. **A:** Sagittal T2-weighted magnetic resonance imaging demonstrates a large thoracic disk herniation compressing and deforming the thoracic cord. **B:** Extensive calcification of the disk-osteophyte complex is appreciable on computed tomography imaging of the thoracic spine. Calcification of a thoracic disk introduces an added degree of complexity to surgical decompression.

Cervical Disk Disease

Cervical disk herniation may involve both the nerve root and spinal cord depending on the volume of the canal and the size of the lesion. Spinal cord compression is uncommon, except with spinal stenosis or massive rupture of a disk. The sites of the most frequent disk herniations are C5-C6 and C6-C7; C4-C5 and C7-T1 are less frequently affected. Movement of the cervical spine is normally incremental and any process contributing to focal stress at individual levels adds to progressive pathologic changes in the disk and to deficits in joint mechanics (**Fig. 113.5**). Development of a new fulcrum of motion above a fusion or congenital block vertebra increases susceptibility to these changes.

The signs and symptoms of cervical disk disease usually begin with stiff neck, reactive splinting of the erector capital muscles, and discomfort at the medial border of the scapula. Radicular paresthesias and pain supervene when the root is more severely compromised. These symptoms are worsened by movements of the head and neck as well as by stretching of the dependent arm.

As compression proceeds, discrete root syndromes appear (see **Table 113.1**). C5 lesions cause pain in the shoulder and dermatomic sensory diminution with weakness and atrophy of the deltoid. C6 lesions cause paresthesias of the thumb and depression of the biceps reflex with weakness and atrophy of that muscle. In C7 lesions, paresthesias may involve the index and middle fingers, and even the thumb with atrophy and weakness in the triceps muscles, wrist extensors, and pectoral muscles as well as a parallel reflex depression. C8 subserves important intrinsic muscle functions in the hand and sensation in the fourth and fifth fingers. Because these are important in discriminatory and fine finger maneuvers, C8 damage may be disabling.

Myelopathy

Large disk protrusions in the thoracic and cervical spine, particularly with concurrent spinal stenosis, may compress the spinal cord resulting in myelopathic signs on clinical exam. Clinical signs of myelopathy reflect injury to upper motor neurons. Reflexes and tone are increased, whereas coordination and balance are diminished. Patients with cervical myelopathy often have difficulty using their hands for fine motor tasks and adopt a broad-based gait to improve balance while upright. Other signs of myelopathy on routine physical exam include Hoffman and Babinski signs, a positive Romberg test, and sustained clonus. Myelopathy is often combined with lower motor neuron weakness and may be subtle if compression of the cord is mild.

DIAGNOSIS

Initial Management and Evaluation

Radiculopathy is a clinical diagnosis based on careful history and physical examination. Immediate diagnostic testing with magnetic resonance imaging (MRI) is not necessary in patients with new-onset radicular pain that have not failed conservative measures. Patients with low back and/or radicular pain should undergo at least 6 weeks of pain control, rest, and physical therapy.

Immediate imaging should be obtained in those patients with acute and/or progressive neurologic deficits, or those in refractory severe pain. Diagnostic imaging is particularly urgent in patients with urinary retention and or saddle anesthesia, signs of cauda equina syndrome. An MRI should also not be delayed in cases with a high clinical suspicion of neoplastic or infectious systemic disease, as symptoms in these patients may be secondary to spinal metastases or epidural abscesses.

FIGURE 113.5 Cervical disk herniation. T2-weighted magnetic resonance imaging shows C5-C6 disk herniation (*dashed line* in **B**) in a patient with radiculopathy in sagittal (**A**) and axial planes (**B**).

In those patients who fail conservative management, MRI should be used to confirm a diagnosis of disk disease before considering invasive treatment. When no correlation exists between radiographic and clinical findings, electromyography and nerve conduction studies can help elucidate the etiology of presenting symptoms.

Considerations in the Cervical Spine

Lesions such as supraspinatus tendinitis, arthritic changes in the acromioclavicular joint, and rotator cuff tears may be difficult to differentiate from cervical root compression, especially because prolonged pain and lack of range of motion lead to atrophy and frozen shoulder in these syndromes. C8 and T1 lesions commonly cause a partial Horner syndrome. A diagnostic workup for syndromes of these levels must include apical lordotic views of the chest, and special care must be taken to rule out pulmonary neoplasms and abnormal cervical ribs.

Other Diagnostic Considerations

Because many disk syndromes are genetic, abnormal skeletal features throughout the spine may be sought on radiographs. These include spinal stenosis, spondylolisthesis, widespread disk disease, or Marfan syndrome. Acquired disorders, such as osteochondritis juvenilis, and metabolic states such as osteoporosis, may contribute to pathologic changes in the disk and adjacent joints, as do several forms of arthritis. Importantly, disk syndromes may be duplicated by tumors (eg, primary or metastatic), infections (eg, epidural abscess), and arachnoiditis. Epidural lipomatosis, a rare cause of low back syndromes, is a complication of steroid therapy.

Imaging and Electrodiagnostic Studies

Magnetic Resonance Imaging

An MRI is the imaging procedure of choice for disk disorders. The MRI identifies spinal cord or nerve root compression and also reveals the degree of degenerative change within the disk. It clearly delineates both intra- and extradural structures and is the ideal screening procedure for a differential diagnosis that includes structural disorders affecting the spinal cord and nerve roots.

Importantly, evidence of degenerative disk disease and even disk rupture on MRI may not correlate with clinically significant pathology that requires intervention. In studies of asymptomatic individuals, bulging and herniated disks have been identified in 50% and 27% of adults, respectively. Abnormal findings on MRI of the lumbar spine in asymptomatic adults do not appear to predict future development of low back pain. In the absence of progressive neurologic deficit or suspicion of systemic illness, such as cancer or infection, MRI should be reserved for those individuals with at least 6 weeks of persistent low back/radicular pain despite conservative therapy (see "Initial Management and Evaluation" section).

Myelography and X-ray

Computed tomography (CT) myelography is more invasive than MRI, exposing patients to the intrathecal administration of contrast as well as ionizing radiation. Accordingly, CT myelography is rarely indicated. It does effectively visualize spinal nerve roots and their trajectory through the neural foramina, particularly the anatomy of the nerve root sleeve. However, myelography is unrevealing in the evaluation of far lateral disk herniations, which occur lateral to the spinal canal and root sleeve. Myelography is useful for patients with intolerance of, or contraindications to, MRI, such as cardiac pacemakers and other implanted electrical devices. In addition, CT myelography may be preferred for patients who have surgically placed spinal implants that produce magnetic artifacts. Plain radiographs effectively depict bony anatomy but not herniated disks. Radiographs do provide valuable information related to spinal alignment and segmental stability prior to surgical intervention.

Electromyography and Nerve Conduction Studies

The primary electrodiagnostic studies used in the evaluation of radiculopathy are electromyography and nerve conduction studies. These studies can be used to accurately identify radiculopathy that has been accompanied by weakness for 3 weeks or more, but they are seldom essential. Electrodiagnostic studies are most useful when radiographic findings do not correlate with clinical presentation.

TREATMENT

Most acute attacks of back pain improve in days or weeks, and only a small minority of patients requires surgery. In one meta-analysis, 82% of patients with acute low back pain returned to work within a month of onset. In the absence of neurologic deficit, conservative treatment should be pursued so long as the patient continues to improve with analgesics and rest for lumbar and cervical disk disorders. Epidural and/or transforaminal steroid injections are a useful adjunct. These interventions reduce inflammation and thereby relieve pressure on the affected nerve root.

Expert Referral

In the acute phase, indications for referral to a treatment specialist are similar to indications for urgent MRI. Patients who present with signs/symptoms of acute or progressive neurologic deficit, including motor weakness, myelopathy, or signs of cauda equina syndrome, should be urgently evaluated by a neurosurgeon or orthopedic surgeon with experience in spine surgery. This referral should not delay MRI, which is an essential component of any potential surgical decision making. Of note, there is no evidence that early referral to a spine surgeon, in the absence of the aforementioned criteria, improves outcome. For those patients who lack acute or progressive neurologic deficit but have persistent symptoms impairing quality of life, surgery can be scheduled on an elective basis. Importantly, no randomized trial demonstrating the benefits of surgery has enrolled patients with less than 6 weeks of conservative therapy.

Lumbar Diskectomy

Lumbar diskectomy is indicated in patients with evidence of nerve root compression on neuroimaging and either corresponding radicular pain refractory to conservative therapy or corresponding acute/progressive weakness. Surgery represents an effective treatment option in properly selected patients, as diskectomy of a herniated lumbar disk fragment almost always results in long-term satisfactory relief of symptoms. Lumbar fusion is rarely required for treatment of radiculopathy from a herniated lumbar disk. Excessively prolonged physiotherapy and bed rest may cause emotional exhaustion, muscle loss, or drug dependence.

Evidence from an early randomized controlled trial by Weber comparing prolonged conservative management to diskectomy

suggests that surgery offers greater relief from radiculopathy caused by herniated lumbar disks in the short term LEVEL 1.[1] However, patients randomized to both surgical and nonsurgical groups experienced considerable symptomatic improvement over time, and the difference between groups was not statistically significant at long-term follow-up. This may be partially explained by unintended crossover between groups, as approximately one-quarter of patients randomized to nonsurgical therapy elected to have a diskectomy presumably due to persistent symptoms with conservative management.

In a large multicenter, prospective, randomized, controlled trial, researchers with the Spine Patient Outcomes Research Trial demonstrated substantial improvement with both surgical and nonsurgical treatment of lumbar disk disease with radiculopathy. Although short-term results were consistently in favor of surgery, differences in primary outcomes were not statistically different LEVEL 1.[2] At long-term follow-up (4 and 8 years), patients treated with surgery demonstrated greater improvement in secondary outcomes, including "sciatica bothersomeness," self-rated improvement, and patient satisfaction with symptoms LEVEL 1.[3] Primary outcomes (bodily pain, physical function, and disability index) also favored surgery, but these differences were not significant between groups. The results of the Spine Patient Outcomes Research Trial research effort were widely touted by the lay press, and some in the medical community, as evidence for the equivalence between modern surgical and nonsurgical treatment techniques. However, as the study authors rightly conclude, "conclusions about the superiority or equivalence of the treatments under study are not warranted based on the intent-to-treat analysis." Crossover between groups again served as a major confounder that may underestimate the relative benefit of surgery, as approximately half (49%) of patients assigned to nonoperative management ultimately elected to have surgery after a trial of conservative therapy.

Surgical techniques for lumbar diskectomy can be broadly segregated into three categories: open diskectomy, microdiskectomy, and minimally invasive diskectomy. Traditional open diskectomy involves a standard laminectomy and is performed with eyepiece magnification. Microdiskectomy is the most commonly performed procedure and typically involves a smaller incision with less bone removal in the form of a hemilaminotomy and use of the operative microscope to remove the offending disk fragment.

Minimally invasive techniques have become extremely common in modern practice. Typically, minimally invasive lumbar diskectomy includes the use of a tubular retractor system inserted through small incisions over a guidewire with fluoroscopic guidance. This technique uses muscle spitting, as opposed to the muscle cutting/detachment inherent to other methods, which its advocates suggest reduces postoperative pain and recovery time. Arts and colleagues randomized 328 patients to minimally invasive versus conventional microdiskectomy for lumbar radiculopathy. At 2-year follow-up, similar functional and clinical outcomes were reported between groups LEVEL 1.[4] A meta-analysis of randomized controlled trials comparing tubular diskectomy to conventional microdiskectomy found that both methods lead to a substantial and equivalent long-term improvement in leg pain. Total complications did not differ between study arms LEVEL 1.[5]

Cervical Diskectomy

Indications for surgery to relieve radiculopathy from disk disease in the cervical spine are similar to the indications for lumbar diskectomy. Good surgical candidates have persistent radicular pain despite at least 6 weeks of conservative treatment or acute/progressive motor weakness. Clinical evidence of myelopathy with radiographic evidence of cord compression from a herniated disk represents an additional indication for diskectomy.

Generally, spinal cord compression requires consideration of decompressive measures as soon as it is recognized. Nerve root syndromes of the cervical spine may be separated into those that require careful supervision and early operation and those that tolerate and may respond to conservative care. The muscles served by C5 may rapidly atrophy, leaving abduction paresis, poor prognosis for restoration of function, and a painful frozen shoulder. C8 is also vulnerable, and unrelieved compression may lead to irreversible atrophy with complex shoulder-arm-hand disorders that include circulatory and sweating abnormalities. C6 and C7 innervate large muscles and tolerate pressure more benignly even for long periods and may have good functional return. Cervical root syndromes are less likely to recur than lumbar disorders, and conservative therapy is worthwhile within the outlines described.

Removal of a cervical herniated disk may be performed either through a posterior laminotomy or through an anterior approach. In most case, particularly in patients with cervical kyphosis, an anterior approach is preferred. Anterior cervical diskectomy with fusion is one of the most successful and widely practiced procedures in spine surgery. By combining anterior decompression with a strut graft to promote fusion across the vacated intervertebral disk space, lordosis can be restored across the segment. Excellent results may be anticipated in appropriately selected patients.

Persson and colleagues conducted a randomized controlled trial comparing anterior cervical diskectomy to nonoperative therapy in 81 patients with clinical and radiologic signs of cervical nerve root compression lasting 12 weeks or more. Patients in the nonoperative arm were prescribed physical therapy and immobilization with a rigid cervical collar. Individuals with clinical signs of myelopathy or radiographic evidence of cord compression were excluded. Patients treated with surgery demonstrated greater improvement in both pain and motor strength at 4 months follow-up. At 1 year, no significant difference in pain remained, but patients in the surgical arm maintained a small advantage in muscle strength LEVEL 1.[6]

Prospective observational studies by Heckmann and Sampath provide further support for the efficacy of anterior cervical diskectomy in the treatment of cervical radiculopathy without myelopathy. At 2-year follow-up, patients who underwent surgery showed greater improvements in both pain and weakness compared to conservatively treated patients. Overall, approximately 75% of patients experienced significant relief from symptoms after surgery.

A primary disadvantage of anterior cervical diskectomy and fusion surgery, particularly in the young, is the development of adjacent segment disease. By fusing cervical vertebrae via the anterior cervical diskectomy with fusion procedure, a rigid segment is produced that acts as a lever arm, increasing the stress on cervical levels immediately adjacent to the fused segment. The cervical disk arthroplasty procedure, or "artificial disk," was developed to preserve motion and to obviate the potentially deleterious effects of adjacent segment stress and degeneration. This procedure is generally reserved for younger patients without significant neck pain, spondylosis, or deformity. Although it remains controversial in certain clinical scenarios, an increasing body of evidence supports the efficacy if cervical disk arthroplasty in carefully selected patients LEVEL 1.[7]

SUMMARY

Radiculopathy resulting from intervertebral disk disease is self-limited in the majority of patients. Symptoms generally improve with rest, pain control, physical therapy, and time. If symptoms persist after at least 6 weeks of conservative therapy, patients should be referred for MRI. If intervertebral disk disease identified on neuroimaging correlates with clinical presentation, patients should be referred to a spine surgeon. More urgent referral should be initiated in the presence of symptoms of cauda equina syndrome, myelopathy, or acute/progressive motor weakness. Randomized controlled trials comparing diskectomy to conservative therapy in the lumbar and cervical spine demonstrate similar long-term outcomes between groups that modestly favor surgery in appropriately selected patients. The short-term benefits of surgery have been more consistently realized across studies. Crossover between randomized arms may contribute to an underestimation of the benefit of surgery, as patients frustrated by the severity of their symptoms and the slow pace of recovery with conservative therapy commonly opt to have surgery.

Cervical and Lumbar Spinal Stenosis 114

Brian J.A. Gill and Paul C. McCormick

KEY POINTS

1. Symptoms in the setting of spinal stenosis are due to direct compression of the surrounding neural and vascular elements.
2. Cervical spondylotic myelopathy is characterized by a spastic gait, difficulty with fine motor control, and proprioceptive sensory loss.
3. Lumbar stenosis presents clinically as neurogenic claudication. This syndrome is characterized by lower extremity pain and numbness, which is exacerbated with walking or standing and relieved with sitting or leaning forward.
4. Magnetic resonance imaging is the imaging modality of choice for confirming a diagnosis of cervical or lumbar stenosis.
5. Asymptomatic patients with radiographic evidence of spinal stenosis rarely warrant surgical intervention.
6. In appropriately selected patients who have failed medical management for spinal stenosis, surgical intervention provides durable symptom relief and improves functional outcomes.

INTRODUCTION

Neck and low back pain are common causes of disability and significant socioeconomic burden.

These symptoms are the third most common cause of personal health care spending in the United States, with an estimated expenditure of 87.6 billion per year. Cervical and lumbar spinal stenosis are the most common causes of neck and low back pain, and they represent the most frequent indications for spine surgery in adults older than 65 years of age. In this chapter, we discuss the epidemiology, biology, diagnosis, and efficacy of the interventions used to manage symptomatic spinal stenosis.

EPIDEMIOLOGY

Simply defined, spinal stenosis refers to the progressive narrowing of the spaces within the spinal column where the spinal cord, nerve roots, and associated vasculature elements pass. This is primarily a radiographic diagnosis, which if clinically significant can present with pain and weakness but is commonly identified on magnetic resonance imaging (MRI) or computed tomography (CT) studies of otherwise asymptomatic patients. Furthermore, not all low back or neck pain is the result of spinal stenosis, even if present on imaging studies. As a result, it has been difficult to assess the true prevalence of radiographic and/or symptomatic spinal stenosis.

The best estimates of spinal stenosis come from the Framingham Study, which found that the prevalence of absolute and relative lumbar stenosis was 22.5% and 7.3%, respectively; this increased to 29.7% and 18.9% in the subsample of patients with clinical symptoms. A larger longitudinal study performed by the same group has shown that 50% of individuals aged 40 to 59 years have baseline degenerative changes, the prevalence of which increased two- to fourfold in those aged 60 to 69 and 70 to 89 years, respectively.

With respect to the cervical spine, Matsumoto et al has shown that degenerative changes in asymptomatic individuals are seen in up to 14% of individuals in their 20s and 87% in their 80s. In a 10-year follow-up study on this population, 81.1% of individuals demonstrated progression of their degenerative findings, and 34.1% of the patients had complaints consistent with symptomatic cervical stenosis. The major finding in all of these studies is that the frequency of degenerative changes in the cervical and lumbar spine increases linearly with age. Similar studies have shown that smoking and obesity increase the risk of the development of clinically significant spinal stenosis.

In a smaller subset of patients, acquired stenosis of the spinal canal may be due to inflammatory joint disorders, which affect the spine and sacroiliac joint known as *spondyloarthropathies*. These disorders include ankylosing spondylitis and reactive arthritis, both of which are associated with the major histocompatibility complex antigen human leukocyte antigen B27, and, unsurprisingly, their prevalence varies worldwide, clustering in areas of human leukocyte antigen B27 positivity.

Diffuse idiopathic skeletal hyperostosis and ossification of the posterior longitudinal ligament are noninflammatory disorders characterized by progressive calcification of the paravertebral ligaments which can cause stenosis, particularly in the cervical spine. Both disorders are more common in men and the elderly; ossification of the posterior longitudinal ligament also has a predilection for individuals of Asian descent.

PATHOBIOLOGY

Spondylosis

Age-related progressive arthritic degeneration of the intervertebral disks and facet joints is the most common cause of spinal stenosis. Collectively, these proliferative changes are referred to as *spondylosis*, and they occur in repetitive biomechanical stress and strain. Normal, albeit accentuated, wear and tear degenerative changes in the spine is the most common cause of spinal stenosis both in the cervical and lumbar spine. The water content of the intervertebral disk and annulus fibrosus declines progressively

with advancing age. Additionally, the intervertebral space narrows and may be obliterated, and the annulus fibrosus protrudes into the spinal canal. Osteophytes form at the margins of the vertebral body, converge on the protruded annulus, and may convert it into a bony ridge or bar. This bar may extend laterally into the intervertebral foramen. These changes all narrow the normal canal or foramina in the spinal column, and this may be exacerbated by concomitant hypertrophy of the ligamentum flavum, synovial cyst formation, overgrowth of the facets, or degenerative spondylolisthesis (anterior slippage of a vertebral body) (Fig. 114.1).

These arthritic changes can affect the central canal where they lead to compression of the spinal cord or cauda equina in the cervical and lumbar spine, respectively; the neural foramina causing compression of the exiting nerve root; or the lateral recesses of the lumbar spine where they cause compression of traveling nerve root. Spinal stenosis tends to develop at the most mobile and mechanically stressed levels. The C5-C6 and C6-C7 levels are the most commonly involved in the cervical spine, whereas L4-L5 and L3-L4 are the most commonly affected lumbar levels.

FIGURE 114.1 Artist depiction of anatomic and pathologic changes that may occur in the setting of cervical stenosis. (Reused with permission from Nouri A, Tetreault L, Singh A, Karadimas SK, Fehlings MG. Degenerative cervical myelopathy: epidemiology, genetics, and pathogenesis. *Spine [Phila Pa 1976]*. 2015;40:E675-E693.)

Congenital Stenosis

Most cases of degenerative spinal stenosis are sporadic in occurrence, although there may be a family history in some patients. The term *congenital spinal stenosis* is a bit of a misnomer because stenosis connotes an acquired narrowing. A *developmentally small spinal canal* is a more accurate term than congenital stenosis. Patients with a developmentally small canal may be more susceptible to develop symptomatic stenosis simply because they have less capacity to accommodate the proliferative degenerative changes associated with the progressive arthritic process of the spine. Patients who have either congenital fusions (ie, Klippel-Feil syndrome) may be prone to develop spinal stenosis at levels adjacent to the fused level.

Myelopathy

Progressive stenosis of the cervical spine due to the aforementioned changes can damage the spinal cord and produce a condition known as *cervical spondylotic myelopathy* (CSM). This disorder is attributed to one or more of three possible mechanisms: (1) direct compression of the spinal cord by bony or fibrous tissue overgrowth, (2) ischemia caused by compromise of the vascular supply to the cord, and (3) repeated trauma in the course of physiologic neck movement.

Pain

Pain in the setting of cervical or lumbar stenosis may be axial (confined to the neck or back) or radicular (radiate to the extremities) in nature. The mechanisms that produce myelopathy are also responsible for radiculopathy, direct compression of the nerve roots, or compression of their blood supply and subsequent ischemia can lead to radicular pain or weakness. The cervical dorsal rami, ventral rami, sympathetic trunks, and sinuvertebral nerves innervate several structures around the cervical spine. These include the synovial joints, intervertebral disks, dura, and overlying musculature. Damage to the nerve endings at any of these sites during spondylosis, or with acute events such as tears in the annulus of the intervertebral disk, can lead to specific patterns of axial neck pain including discogenic or facet joint pain syndromes. Similar mechanisms mediate axial pain syndromes in the lumbar spine.

TABLE 114.1 Clinical Manifestations of Cervical Spondylotic Myelopathy[a]

Symptoms or Signs	% of Patients

DIAGNOSIS

Clinical Manifestations

Cervical Stenosis

Patients usually present with either myelopathy or radiculopathy. A combined myeloradicular presentation is unusual but can be seen in myelopathic patients with concomitant neural foraminal stenosis. The most common symptom of myelopathy is a spastic gait disorder (Table 114.1). Axial neck pain may be prominent and chronic in nature. Clumsiness of the hands and loss of dexterity and fine motor control with tasks such as writing, typing, and buttoning are common early complaints in patients with CSM. Weakness and wasting of the hands may be seen but only as the condition becomes more advanced. Proximal arm weakness with difficulty lifting the arm over the head is the presenting complaint in a small number of patients. Bowel and bladder complaints are not common in the early stages of CSM but may be seen if it remains untreated.

The course of cervical stenosis is slowly progressive, but its natural history is not well delineated. In some patients, the condition may wax and wane with periods of relative quiescence or even improvement followed by progressive worsening. Acute worsening precipitated by a fall or other traumatic event may exacerbate existing symptoms or produce a central cord syndrome that is characterized by sudden-onset distal upper extremity numbness and weakness with relative preservation of lower extremity function. These injuries most likely occur from sudden hyperextension of the cervical spine with buckling of the ligamentum flavum causing impingement of the spinal cord. Spontaneous substantial recovery from acute central cord syndromes commonly occurs.

Lumbar Stenosis

The classic presentation of patients with lumbar stenosis is neurogenic claudication. Patients typically present with symptoms of lower extremity pain, weakness, and/or numbness with standing or walking. These symptoms are reliably relieved with sitting or leaning forward because these positions straighten the ligamentum flavum and increase the dimensions of the spinal canal. In comparison, upright positions increase the degree of lumbar stenosis by buckling of the ligamentum flavum into the spinal canal. Symptoms can vary from patient to patient in terms of the quality, distribution, severity, and duration. Most patients do not have a fixed neurologic deficit by the time of clinical presentation. Fixed deficits (eg, footdrop) or cauda equina syndrome is now rare, although they can be seen in long-standing untreated patients or acute presentations from a large central disk herniation.

Physical Examination

A thorough physical and neurologic examination should be performed when evaluating patients with complaints of neck or back pain. This includes a complete assessment of the patient's strength, sensation, reflexes, gait, and balance. Cervical spine and shoulder pathologies may have similar clinical presentations and patients frequently experience both simultaneously. A shoulder examination should be performed in patients presenting with neck pain to evaluate for a rotator cuff tear or chronic acromioclavicular joint injuries masquerading as cervical problems. Similarly, hip pain is a common mimic of low back pain, and clinical pain provocation testing can be used to differentiate the two. If present, hip pain can be reproduced by flexion, abduction, and external rotation test of the hip.

Radiographic Studies

The diagnosis of cervical or lumbar stenosis is confirmed with imaging of the spinal canal. As mentioned earlier in the chapter, it is important to appreciate that patients may have radiographic evidence of spinal stenosis without neurologic signs or symptoms. With few exceptions, these asymptomatic patients are not in need of treatment.

Plain Radiography

Formerly, the most important diagnostic tests were plain radiographs of the spine. Although other imaging modalities have largely supplanted x-rays, they still play an important role in imaging patients with spinal stenosis. Plain radiographs can demonstrate early osteophyte formation and disk space narrowing. The anteroposterior and lateral views provide information on the patient's overall alignment. Additionally, flexion and extension radiographs can be used to evaluate for any concomitant spinal instability.

Computed Tomography and Computed Tomography Myelography

Noncontrast CT scans provide complementary information to that obtained from MRI sequences and can help to differentiate an ossified disk from a soft disk herniation. This modality is also particularly useful for delineating the bony anatomy of patients prior to surgery. CT myelography is an invasive test and has been replaced by MRI for the evaluation of cervical and lumbar stenosis. However, this study may be of greater utility in patients with prior surgery where postoperative changes make MRI studies difficult to interpret. Additionally, it remains an option for symptomatic patients with contraindications to MRI (eg, due to implanted medical devices).

Magnetic Resonance Imaging

MRI is the imaging modality of choice for the evaluation of both cervical and lumbar stenosis. It is noninvasive and provides excellent resolution of the spinal cord, exiting nerve roots, and cauda equina (**Fig. 114.2**) as well as the surrounding soft tissue structures. MRI also allows the treating physician to evaluate for a range of alternative diagnoses including Chiari malformations, vascular malformations, spinal tumors, syringomyelia or demyelinating conditions such as multiple sclerosis.

Additional Tests

Electrodiagnostic studies such somatosensory-evoked potentials and electromyography (EMG) add little to aid in diagnosis of either cervical or lumbar stenosis. The diagnostic utility of transcranial magnetic stimulation remains to be ascertained, but motor-evoked potentials may be more contributory than sensory potentials. There is little role for cerebrospinal fluid (CSF) analysis. If a lumbar tap is undertaken, the CSF profile is usually normal or the protein concentration may be slightly elevated (50-100 mg/dL). Higher protein levels or CSF pleocytosis should raise the question of multiple sclerosis or tumor, including meningeal carcinomatosis.

MANAGEMENT

Cervical Stenosis

The treatment of cervical stenosis depends on many factors. As previously noted, radiographic stenosis in the absence of signs or symptoms rarely necessitates intervention. Occasionally, a patient with severe stenosis (<7 mm canal diameter) and an intramedullary signal abnormality within the spinal cord may present with little or no neurologic symptoms. In these patients, preemptive surgical decompression may be offered, but it is not clear if the benefit of surgery outweighs the risks in this patient population. Often, patients with minimal or no neurologic signs or symptoms are followed both clinically and with imaging over time. Surgical decompression is usually recommended if clinical progression is documented.

Patients with radicular symptoms from nerve root compression from foraminal stenosis are initially managed with conservative measures such as activity modulation, physical therapy, judicious use of anti-inflammatory medications, and/or steroidal spinal injections. Surgery for decompression of the nerve root either through a posterior cervical foraminotomy or an anterior cervical diskectomy and fusion (ACDF) is an option for patients with persistent radiculopathy that is not responsive to conservative management.

The natural history of CSM varies greatly and is unpredictable in individual patients. In rare instances, conservative treatment with physical therapy for gait training and neck immobilization with a firm collar may be appropriate for patients with mild myelopathy. In these cases, surgery should be considered if the myelopathy progresses despite conservative treatment. There is often no ideal surgical approach for patients with CSM, rather the chosen intervention depends on a variety of factors. Ventral compressive pathology may be better addressed with an anterior approach such as an ACDF, whereas a posterior approach may be better suited for instances of multilevel compression. Similarly, while pathology at the level of the disc space is easily addressed with an ACDF, a corpectomy (surgical removal of the vertebral body) may be needed if the site of compression lies behind the vertebral body. Patient factors also play an important role in the surgical decision making. Elderly patients or those with a history of swallowing or vocal cord disfunction are not ideal candidates for anterior procedures because they are at an increased risk for dysphagia postoperatively. All of these aspects must be considered and discussed with the patient prior to surgical intervention.

Lumbar Stenosis

Unlike cervical stenosis, most patients with lumbar stenosis do not have a neurologic deficit. As a result of this, treatment options are more variable. For patients with mild symptoms, conservative management with activity modification, physical therapy, and/or periodic epidural steroid injections may provide durable stability or even improvement from the symptoms of

FIGURE 114.2 **A:** A normal sagittal T2-weighted magnetic resonance imaging (MRI) of the lumbar spine. **B:** A normal axial T2-weighted MRI of the lumbar spine. **C:** Sagittal T2-weighted MRI of the lumbar spine demonstrating severe lumbar stenosis at L4-L5, spondylolisthesis of L4 on L5, and multilevel loss of intervertebral disk height. **D:** Corresponding axial T2-weighted MRI of the lumbar spine at L4-L5 showing facet hypertrophy, facet joint effusion and thickening of the ligamentum flavum.

lumbar stenosis. Should the patient report worsening symptoms, function or quality of life despite a trial of conservative management, then surgical intervention for decompression may be offered.

As with cervical stenosis, a multitude of factors dictates the chosen surgical intervention for patients who have failed medical management of symptomatic lumbar stenosis. This includes location of the compressive pathology, spinal alignment, spinal stability, surgical history, and the health of the patient. Surgical options include decompressive procedures alone (laminectomy, laminectomy with diskectomy) or decompression and fusion procedures such as a transforaminal lumbar interbody fusion. The latter procedure is often preferred in patients who have severe degenerative disease with spondylolisthesis, recurrent disk herniations following surgical management, or radiculopathy caused by foraminal stenosis from loss of disk height.

OUTCOMES

A large-scale randomized trial of medical versus surgical management of cervical stenosis has yet to be performed. Despite this, there are several large noncomparative prospective studies, which demonstrate the clinical benefit of surgical intervention on patients with cervical stenosis. Fehlings et al performed a multicenter prospective study of 278 patients who underwent surgical management of CSM. At 1-year follow-up, they observed significant improvements in functional outcome, disability outcome, and health-related quality of life regardless of the underlying etiology or surgical approach. Subsequent prospective studies have yielded similar results. Thus, while the study design precludes a discussion of the absolute efficacy of surgery in comparison to medical management, the substantial variation in both the pathology addressed and the employed surgical approach would suggest that these results are generalizable.

The Spine Patient Outcomes Research Trial provides level 1 evidence of both the efficacy and durability of spinal decompression through lumbar laminectomy to relieve the symptoms of lumbar stenosis in appropriately selected patients who have failed to improve with standard nonoperative measures LEVEL 1.[1,2] Additionally, level 1 evidence provided by the Spine Patient Outcomes Research Trial also demonstrated the efficacy and durability of lumbar decompression and fusion (eg, transforaminal lumbar interbody fusion) for patients with lumbar stenosis and degenerative spondylolisthesis LEVEL 1.[3,4]

115 Acquired and Hereditary Myelopathies

Natalie Weathered and Noam Y. Harel

KEY POINTS

1. The differential diagnosis of nontraumatic myelopathies is broad and requires a careful history to narrow the list and guide test selection.
2. Baseline demographics, acuity of onset, and time to nadir may be the most important historical features for narrowing the differential.
3. In cases of suspected infectious or inflammatory etiology, contrasted magnetic resonance imaging of the entire neuraxis is indicated to evaluate for asymptomatic lesions.
4. Basic lumbar puncture cell count and protein profiles in combination with extended tests provide critical information.
5. For most myelopathies, rapid diagnosis and initiation of treatment is of the utmost importance to prevent further neurologic decline.

INTRODUCTION

Myelopathy indicates pathology of the spinal cord leading to dysfunction of central motor and sensory circuits, as opposed to radiculopathy (pathology of spinal roots), which affects solely peripheral circuits. Numerous conditions may cause myelopathy (**Table 115.1**). This chapter expands on key inflammatory, infectious, vascular, metabolic, genetic, and toxic insults. We also offer clinical pearls for diagnosing the cause of acute myelopathy (**Table 115.2**) and for differentiating acute, subacute and chronic myelopathy (**Table 115.3**).

SYRINGOMYELIA

A syrinx is an intramedullary fluid-filled cavity typically found within the cervical to midthoracic spinal cord (**Fig. 115.1**), but extension down to the conus medullaris is also possible as is upward extension to the brainstem in which case it is called *syringobulbia*. The cavity is most commonly filled with cerebrospinal fluid (CSF). However, syringomyelia should be regarded as distinct from simple cystic expansion of the central canal for which the term *hydromyelia* applies.

Epidemiology

The prevalence of syringomyelia in Western countries is approximately 8.4 cases per 100,000. It typically presents either congenitally or in the third to fourth decade of life, and men are more frequently affected than women. It uncommonly presents in late-adult years.

Pathobiology

Generally speaking, primary and secondary syringomyelia arise from an impairment of normal CSF flow dynamics. Although congenital cases of isolated primary syringomyelia do exist, congenital syringomyelia more often arises associated with Chiari type 1 malformation, in which an abnormally small posterior fossa alters CSF flow.

Spinal cord tumors may also cause secondary syringomyelia by altering local CSF flow dynamics. Additionally, syringomyelia may be seen in the chronic phase after trauma, either as an ex vacuo lesion that persists after absorption of an intramedullary hematoma or due to local inflammation of the pia-arachnoid resulting in adhesions between the meninges and spinal cord. In animal models, these adhesions lead to ischemia, demyelination, and ultimately, cavitation.

Clinical Features

Cervicothoracic syringomyelia classically presents with insidious onset of a cape-like distribution of decreased pain and temperature sensation in the back, arms, and hands, which occurs due to disruption of the crossing spinothalamic tracts. Sometimes, the patient may be unaware of sensory loss until burns or abrasions on the hands are noticed after the fact. There may be varying degrees of weakness in the arms (lower motor neuron type due to involvement of cervical anterior horn cells) and legs (upper motor neuron type due to involvement of lateral corticospinal fibers). A Horner syndrome may be present if a cervicothoracic syrinx affects the intermediolateral columns. Bowel and bladder function are generally preserved unless the syrinx extends toward the sacral cord segments.

Diagnosis

Magnetic resonance imaging (MRI) allows visualization not only of the syrinx but also of any associated abnormalities such as Chiari malformation, neoplasm, arachnoid granulations, or tethered cord. Full cord imaging should be strongly considered. The MRI CSF flow studies may also be useful in guiding treatment. There are no biomarkers associated with syringomyelia. The CSF is often normal or may have a nonspecific, mild elevation in protein.

Management

Conservative observation is warranted in cases with no or only minor symptoms and in cases of Chiari malformation with tonsillar herniation less than 5 mm below the foramen magnum in the setting of normal CSF flow studies. In more severe cases of Chiari, however, posterior fossa decompression and cervical

TABLE 115.2 Clinical Pearls for a Patient With Acute Myelopathy but Negative Magnetic Resonance Imaging

1. Initial spinal cord MRI can be negative in up to 20% of cases.
2. Did you image the right level? Sometimes, what appears to be a thoracic sensory level actually comes from a cervical lesion. Total spine MRI is warranted in any case of acute nonstructural myelopathy. Alternatively, is there any possibility the symptoms arose from a brain lesion?
3. Ensure the MRI was done with contrast as it will increase sensitivity for both active demyelination as well as vascular lesions.
4. Some lesions can radiographically resolve with time, so if the MRI is done late you may not identify the lesion.
5. Use the history to guide you.
   A. Stepwise decline? Consider an inflammatory or vascular etiology.
   B. Nadir within 12 h of onset? Consider vascular etiology.
   C. Prior bariatric surgery or denture use? Recent nitrous oxide exposure? Consider nutritional deficiency including vitamin B_{12}, folate, and copper.
   D. Prior radiation history?
   E. Pertinent family history? Consider hereditary spastic paraplegia.
   F. Travel history? Consider Lyme or HTLV.
   G. History of sexually transmitted diseases? Consider HIV or syphilis.
   H. Rheumatologic symptoms such as dry mouth, rash, history of miscarriages, or thrombosis? Consider diseases such as Sjögren syndrome, systemic lupus erythematosus, and sarcoidosis.
   I. Weight loss or smoking history? Consider a neoplastic or paraneoplastic etiology.
6. Have a low threshold to send treatable causes of myelopathy including vitamin B_{12}, folate, copper, Lyme, HIV, RPR, erythrocyte sedimentation rate, C-reactive protein, SSA (Ro), SSB (La), ANA, dsDNA, and ACE.

Abbreviations: ACE, angiotensin-converting enzyme; ANA, antinuclear antibodies; dsDNA, double-stranded DNA; HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus; MRI, magnetic resonance imaging; RPR, rapid plasma reagin.

TABLE 115.3 Clinical Findings of Acute, Subacute, and Chronic Nontraumatic Myelopathy

laminectomy with or without duraplasty is frequently pursued in hopes of restoring normal CSF flow dynamics.

In cases of syringomyelia secondary to neoplasm, if resection is not possible, then fenestration or marsupialization of the syrinx may be attempted. Lysis of adhesions and/or shunting of the syrinx to the pleural or peritoneal cavities is also performed, although the benefits have not been proven and are very difficult to predict in individual patients.

Nonoperative management includes medications to treat neuropathic pain. Occasionally, trials of diuretics are attempted in the hope of reducing syrinx size. However, this is rarely successful.

FIGURE 115.1 Syringomyelia on a T2-weighted magnetic resonance imaging. The syrinx, which appears as a high-intensity linear lesion in the central cord, extends from C4 to C7. (From Peleggi AF, Lovely TJ. Treatment of delayed Chiari malformation and syringomyelia after lumboperitoneal shunt placement: case report and treatment recommendations. *Surg Neurol Int*. 2012;3:101, with permission.)

Outcome

A study by Alfieri and Pinna found that surgical posterior fossa decompression for Chiari type 1 malformation associated with syringomyelia tends to be well tolerated with few complications. Additionally, 93.4% of patients experienced some degree of clinical improvement.

In contrast, a study of surgical treatment for posttraumatic syringomyelia showed much lower clinical success rates, with only 51% of patients reporting clinical improvement. Forty-one percent of patients experienced no clinical change, and 8% had further clinical deterioration. Notably, among those patients in whom surgery was not recommended based on lack of significant neurologic symptoms, 84% remained stable at 10 years. The high progression-free rate and the unsure evidence for surgical efficacy both argue for the clinician to take a conservative, watchful approach to posttraumatic syringomyelia if at all possible.

NEOPLASTIC MYELOPATHY

Neoplasm should be high on the differential anytime someone presents with myelopathic symptoms of unknown origin. Metastatic disease is much more common than a primary spinal tumor. In fact, an estimated 12% to 20% of patients with systemic cancer present with spinal metastasis as the initial cause of symptoms. Primary spinal cord tumors are much rarer with an estimated prevalence of 0.74 cases per 100,000.

It is important to bear in mind that not all myelopathy in the setting of neoplasm is a direct consequence of the neoplasm itself but rather may be secondary to radiation injury, chemotherapy toxicity, or a paraneoplastic disorder. Primary spinal neoplasms are discussed in Chapter 107. Further information on metastatic neoplasm may also be reviewed in Chapter 101.

Epidemiology

The cancers that most frequently metastasize to the spinal column are lung, breast, renal, hematopoietic, melanoma, prostate, and gastrointestinal. At least 95% of spinal metastases are extradural, usually to the vertebrae, where many remain asymptomatic. Autopsy studies suggest that over 30% of patients with advanced systemic cancer have pathologic evidence of vertebral metastases at the time of death. In the rostrocaudal axis, the majority of spinal metastases localize to the lumbar spine. However, due to the narrower diameter of the thoracic spinal canal, most symptomatic metastases are within the thoracic spine.

Pathobiology

Most spinal metastases travel hematologically either through the arterial system or retrogradely through Batson venous plexus. As the vertebral column comprises a large proportion of the body's bone marrow, which is rich in growth factors, the vertebrae may provide a particularly hospitable environment for metastatic cells. Leptomeningeal metastases can also result from either extension from nearby bone or spread through the CSF.

Clinical Features

In addition to the usual myelopathic symptoms of weakness, sensory loss, and urogenital dysfunction, spinal neoplasms are often marked by pain. The pain may be local (from periosteal irritation or pathologic vertebral compression deformity), or radicular, or both. It may accompany myelopathic symptoms acutely, or it may precede myelopathic symptoms by weeks to months. Although nonspecific, red flags of concern for a cancerous cause of back pain include age older than 60 years at onset, associated weight loss, worse at night, thoracic rather than lumbar pain, and tenderness to palpation. The rate of symptom progression may range from slowly progressive to an acute onset (such as a pathologic vertebral fracture secondary to intravertebral tumor). In addition, metastases may alter arterial perfusion and/or venous drainage, resulting in acute ischemia, hemorrhage, or venous compression.

Diagnosis

Although a computed tomography (CT) scan performs well at detecting bony metastases, MRI with contrast remains the test of choice, as it visualizes the extent of cord and soft-tissue involvement as well as vasogenic and cytotoxic edema. If a neoplasm is identified, full neuraxis imaging should be completed to evaluate for additional lesions, as these may alter treatment and prognosis. Additionally, if the patient is not otherwise known to have cancer, then a full assessment for the primary tumor should be initiated. If the spinal lesion is intradural, a high-volume lumbar puncture should be sent for cytology and flow cytometry although the sensitivity of these studies is not high. Ultimately, biopsy of either the spinal lesion or a suspected primary tumor source remains the diagnostic gold standard.

Management

The mainstay of treatment for spinal metastases has traditionally been glucocorticoid and radiation therapy. Radiation tends to be well tolerated, and 65% to 80% of patients report symptomatic improvement. High-dose corticosteroids such as dexamethasone 100 mg intravenous (IV) push, followed by 6 to 10 mg every 6 hours with a rapid taper over the next few days, are often used concurrently for symptom management. With improvements in technical approaches, surgical decompression has become a critical part of the spinal metastasis treatment armamentarium. A randomized trial has shown that decompressive surgical resection plus radiation therapy for acute paraplegia results in greater ability to walk (84% vs 57%) and a better chance of regaining the ability to walk (62% vs 19%), compared to radiation therapy alone LEVEL 1.[1] Other accumulated case series and studies have suggested that higher preoperative ambulatory function and shorter time between symptom onset and surgery strongly improve postsurgical prognosis.

Outcome

The prognosis after diagnosis of a spinal metastasis remains poor, with an average life expectancy of 4 to 15 months. The emphasis in management, therefore, is typically in maintaining the highest quality of life possible.

INFECTIOUS MYELOPATHY

Numerous infectious causes of myelopathy may induce symptoms through direct neuroinvasion, compression, or inflammation. Symptoms may occur at the time of the acute infection, as in the case of viral myelitis, meningoencephalitis, or abscess, or they may be delayed by days to weeks as in the case of postinfectious or postvaccination myelitis, or even years in the case of neurosyphilis or human immunodeficiency virus (HIV).

Viral Myelitis

Epidemiology

The true incidence of viral myelitis is unknown. Worldwide, the viral syndrome of acute flaccid paralysis, one form of viral myelitis, occurs in approximately 40 per 1,000,000 individuals per year. Cases of transverse myelitis number approximately 1 to 4 cases per 1,000,000 individuals per year. Viral myelitis tends to be more common in the summer and early fall with a bimodal incidence peak in adolescence and the fourth decade of life. Prior to widespread vaccination, polio accounted for the vast majority of cases of acute flaccid paralysis. More recently, West Nile virus (WNV), Japanese encephalitis, and enteroviruses A71 or D68 are the more likely culprits.

Pathobiology

Viral myelitis may occur through direct cellular toxicity or through parainfectious inflammation. In particular, anterior horn cells are often targeted by enteroviruses (including poliovirus, coxsackieviruses A and B, echovirus, enteroviruses A71 and D68) and flaviviruses (WNV, Japanese encephalitis, tick-borne encephalitis). In contrast, herpesviruses, including herpes simplex virus, varicella-zoster virus, cytomegalovirus, and Epstein-Barr virus, have a higher predilection for glial cells of the white matter and sensory neurons in the dorsal horn.

Clinical Features

Acute flaccid paralysis typically presents with fever and headache followed a few days later by the onset of flaccid paralysis of at least one extremity. Alterations in cognition may be seen, reflecting a common association between flaccid paralysis and meningitis and encephalitis. Sensory symptoms and alterations in bowel and bladder control are notably absent. In comparison, inflammatory transverse myelitis often has prominent sensory (usually symmetric) and bowel/bladder abnormalities in addition to weakness with or without cognitive symptoms that evolves over the period of hours to days.

Diagnosis

An MRI with and without contrast may show evidence of edema, demyelination, meningeal enhancement, or necrosis. In addition to cord imaging, brain MRI is warranted to evaluate for intracranial involvement—abnormalities of the deep gray matter indicate viral encephalitis, whereas white matter findings would redirect the diagnosis toward an autoimmune etiology such as postviral or parainfectious inflammation, multiple sclerosis (MS), or neuromyelitis optica (NMO) spectrum disorder.

All patients with suspected viral myelitis should undergo lumbar puncture. Typical CSF findings include pleocytosis with a lymphocytic or mononuclear predominance, normal to low-normal glucose, but elevated total protein. Additionally, many pathogenic viruses may be directly detected within CSF using

either polymerase chain reaction amplification of viral nucleic acid or specific antibody titers.

Management

In the setting of suspected viral myelitis, supportive care and prevention of complications are fundamental. Specific antiviral medications include IV acyclovir, which is typically started empirically upon presentation and may be discontinued if testing for herpes simplex virus and varicella-zoster virus are negative. If cytomegalovirus is suspected in the setting of HIV or other type of immunosuppression, then it would be reasonable to start ganciclovir and foscarnet. If the pathogen is WNV, there is mixed data supporting the use of IV immunoglobulin and interferon alfa-2b. Finally, to combat parainfectious inflammation, IV methylprednisolone is often used in parallel with these other treatments.

Outcome

Prognosis depends in no small part on whether the damage involves gray matter or white matter, with better recovery in the latter. Age, severity of abnormalities, and timing of initiation of specific treatment also affect recovery.

Human T-cell Lymphotropic Virus-Associated Myelopathy (Tropical Spastic Paraparesis)

Epidemiology

The HTLV types 1 and 2 cause insidious, progressive myelopathy in approximately 20 million people worldwide, with the highest infection rates in Japan, South America, the Caribbean, and equatorial Africa. Similar to HIV, HTLV transmission generally occurs as a result of unprotected sex, mother-to-child via breastfeeding, sharing of needles, or blood transfusions. The HTLV can result in either an aggressive T-cell leukemia affecting an estimated 3% to 5% of infected individuals, or it can cause a spastic paraparesis in approximately 0.25% to 3% of infected individuals. Among HTLV-positive individuals, women are 1.5 to 3.5 times more likely to develop HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP) than men and may experience a faster progression of disease.

Pathobiology

Like HIV, HTLV predominantly infects $CD4^+$ T lymphocytes. As a retrovirus, it reverse transcribes its RNA genome into DNA that then integrates into the host genome as a provirus. How HTLV infection leads to chronic, inflammatory/demyelinating myelopathy is not well understood. Autopsy studies show perivascular infiltrates containing HTLV-infected lymphocytes as well as multiple inflammatory cytokines resulting in breakdown of the blood-brain barrier.

Clinical Features

The HAM/TSP is an insidious disease that begins initially with subtle weakness or stiffness of the lower extremities, followed by progression—without remission—toward spastic paraparesis and spastic bladder. Paresthesias in the lower extremities are also common, although sensory levels are not usually seen.

Diagnosis

Because individuals with HAM/TSP symptoms are generally unaware of HTLV infection, the clinician must have an appropriate index of suspicion depending on patient demographics and symptom time course.

In the early stages of the disease, MRI is often unremarkable. With progression, nonspecific subcortical and periventricular white matter demyelinating lesions appear in the brain followed eventually by spinal cord atrophy.

Lumbar puncture typically shows mild pleocytosis with elevated total protein and normal glucose. The HTLV-1 antibodies and a proviral load can be detected in the CSF. Oligoclonal bands (OCB) and evidence of intrathecal immunoglobulin G (IgG) synthesis are often present. The HTLV antibodies are present in serum as well.

Management

Several antiretroviral drugs used against HIV have been trialed against HTLV, so far without success. In the cancer literature, there are some reports of decreased HTLV-1 expression with interferon-α treatment. There are also ongoing trials in Japan investigating the benefit of an anti-C-C chemokine receptor type 4 (CCR4) monoclonal antibody, mogamulizumab, for treatment of HAM/TSP. For now, the mainstays of treatment are symptomatic, with immune-modulating medications such as corticosteroids and cyclosporine used in an attempt to improve HAM/TSP symptoms.

Outcome

The HAM/TSP remains a chronic, progressive, untreatable disease. Patients almost invariably become wheelchair bound with significant bladder and bowel dysfunction.

INFLAMMATORY MYELOPATHY

Noninfectious causes of inflammatory transverse myelitis (see Chapter 72), neuromyelitis optica (Chapter 73), myelin oligodendrocyte glycoprotein IgG (MOG-IgG)-associated disease, acute disseminated encephalomyelitis, systemic lupus erythematosus (SLE), Sjögren syndrome, mixed connective tissue disease, sarcoidosis (Chapter 75), Behçet disease, paraneoplastic syndromes (see Chapter 108), and others that remain to be identified. It is important to note that the cause remains unidentified in up to 30% of cases of spinal cord inflammation resulting in the diagnosis of idiopathic transverse myelitis.

Clinical Features

As with any other cause of myelopathy, symptoms of inflammatory myelopathy depend on the location of the lesion. Most classically, patients present with sensory symptoms, typically in the legs and often with a sensory level associated with bladder dysfunction. Symptoms may progress to include motor deficits over the course of hours to days.

Diagnosis

Brain and total spine MRI with and without contrast are essential. An MRI often reveals T2-hyperintense white matter lesions, which may have contrast enhancement (Fig. 115.2). The pattern of cord and brain MRI involvement may help narrow the differential—for example, longitudinally extensive cord lesions suggest NMO or MOG-IgG–associated disease, whereas deep brain gray matter lesions suggest acute disseminated encephalomyelitis. However, as many as 40% of cases may not show any MRI abnormality. The

FIGURE 115.2 A magnetic resonance imaging showing a transverse myelitis lesion (the lesion is the lighter, oval shape at center right). This magnetic resonance image was taken 3 months after patient recovered. (From Gaillard F. Transverse myelitis. Radiopaedia Web site. http://radiopaedia.org/cases/transversemyelitis. Accessed April 25, 2015.)

CSF studies, if done, should include testing for OCB and IgG synthesis rate. Although not highly specific, several of the most common inflammatory myelopathies are associated with characteristic CSF profiles. For example, MS tends to feature normal protein, lack of pleocytosis, and positive OCB/IgG synthesis; in contrast, NMO usually demonstrates increased protein and cell count and a lower rate of positive OCB/IgG synthesis. Specific (although not always sensitive) serum and CSF biomarkers include aquaporin-4 antibody (NMO), MOG-IgG, angiotensin-converting enzyme (sarcoidosis), antinuclear and anti–double-stranded DNA antibodies (SLE), anti-Ro/SSA (Ro) antibodies, anti-La/SSB (La) antibodies (Sjögren syndrome), anti–scl-70 antibodies (scleroderma), and paraneoplastic antibodies. Visual- and somatosensory-evoked potentials may be useful ancillary tests if MRI and CSF are unrevealing. If there is concern for a paraneoplastic process, systemic body imaging such as CT or CT–positron emission tomography is warranted. In up to 30% of cases, none of these studies are abnormal. These cases earn the diagnostic label of idiopathic transverse myelitis, a label that has steadily become less frequent due to improved diagnostic understanding.

Management

Once infection is ruled out, most cases of paraparesis related to acute inflammatory myelopathy are treated with an empirical 3- to 5-day course of IV corticosteroids, most commonly IV methylprednisolone 1,000 mg daily. More aggressive diseases such as NMO, SLE, Sjögren scleroderma, and others are often also treated with plasmapheresis or IV immunoglobulin. When the diagnosis points to a chronic inflammatory myelopathy, disease-modifying therapy is typically initiated. For example, maintenance rituximab infusions are often given for NMO. An exception is for suspected monophasic transverse myelitis, in which case it is reasonable to follow the patient clinically without initiation of a chronic medication unless a relapse occurs.

Outcome

Prognosis varies widely depending on the disease, the extent of the lesion, the rate of symptom progression, and the patient's age. Disease course may be monophasic or relapsing, with complete remission or permanent disability.

VASCULAR MYELOPATHY

Spinal Cord Infarction

Epidemiology

Compared to cerebrovascular ischemia, spinal cord infarction is quite rare, accounting for only 1% to 2% of vascular neurologic deficits and 5% to 8% of all acute myelopathies with a known diagnosis. In one small study by Cheshire and colleagues, men were almost twice as likely to experience an infarction of the spinal cord as women, but to our knowledge, this has not been studied in a larger context.

Pathobiology

The spinal cord is perfused by the anterior spinal artery and two posterior spinal arteries with the anterior spinal artery supplying the anterior two-thirds of the cord and the posterior spinal arteries supplying the remaining third. Most commonly, the anterior spinal artery forms from a merging of two branches that arise from the V4 segments of the vertebral arteries, although variations exist. However, given the length of the anterior spinal artery, it receives additional supply from feeder anterior radiculomedullary arteries that stem from branches off of the aorta. The most well-known of these feeders is the artery of Adamkiewicz. These branches are variable and typically leave portions of the spinal cord, especially the lower thoracic, vulnerable to watershed ischemia. The vast majority of spinal infarcts occur in the territory supplied by the anterior spinal artery (see Chapter 17, **Fig. 17.2**). Therefore, the most common causes of spinal cord ischemia are secondary to aortic pathology and injury, such as dissection, traumatic rupture, and surgical procedures. Additionally, traditional causes of stroke in the cerebral vasculature can also cause stroke in the spinal cord vasculature—therefore, etiologies such as cardioembolism, hypercoagulable state, atherosclerosis, and vasculitis should be considered.

Clinical Features

Symptom onset typically occurs acutely over minutes to hours, although some patients experience a slower progression of symptoms in the setting of arterial insufficiency. Back pain frequently accompanies other typical myelopathic symptoms. On acute exam, flaccid paralysis and a sensory level to pinprick and temperature below the level of the ischemic lesion will usually be present. Vibration and proprioception are relatively but not completely preserved, as the dorsal columns

are supplied by the posterior spinal arteries. Reflexes are initially reduced or absent but transition to hyperreflexia over subsequent days to weeks.

Diagnosis

When cord ischemia is suspected, special attention should be paid to diffusion-weighted and apparent diffusion coefficient MRI sequences. However, due to difficulties with resolution in the spinal canal, a negative scan does not rule out the diagnosis of ischemia, especially in the first few hours after presentation. There are no specific laboratory abnormalities to confirm the diagnosis. In fact, in the setting of acute nontraumatic myelopathy, a "nondiagnostic" CSF profile without evidence of inflammation should raise cord ischemia prominently on the differential diagnosis. Conventional digital subtraction angiography should be strongly considered under circumstances of high clinical suspicion. As part of the diagnostic workup and to guide secondary prevention, an echocardiogram, telemetry, a lipid panel, and hemoglobin A_{1c} are typically ordered, along with a hypercoagulable disease workup if the patient is younger than age 50 years or has a concerning family history.

Management

No randomized trials have looked at treatment of acute spinal cord infarction as a unique entity.

Induced hypertension with phenylephrine (20-100 μg/min) in association with spinal drainage to reduce CSF pressure (<5 cm H_2O) and increase spinal cord perfusion pressure has been described, in particular when spinal cord infarction occurs as a complication of aortic aneurysm surgery.

There are very few reports of use of tissue plasminogen activator for the treatment of acute spinal cord infarction. This is most likely a result of the broad differential diagnosis at the time of acute paraplegia (see **Table 115.1**) as well as many causes of spinal cord infarction, such as aortic surgery or aortic dissection, serving as contraindications to thrombolysis.

Outcome

The classic teaching is that prognosis for recovery of motor or sphincter function after a spinal infarct is quite poor. However, multiple small studies have shown that functional recovery of, especially, ambulation, but even bladder control, is possible.

Spinal Arteriovenous Malformations and Fistulas

Epidemiology

Arteriovenous malformations (AVMs) are inappropriate arteriovenous connections involving arteries that normally supply neural tissue. In contrast, dural arteriovenous fistulas (DAVFs) are improper connections that involve arteries serving nerve roots and meninges (**Fig 115.3**). The vast majority, approximately 70%, of all spinal vascular malformations are DAVF. The DAVF occur most frequently after the fourth decade of life and are more common in men than women. Intradural AVF are most common within the lower thoracic and lumbar spine. Extradural AVF are most common within the cervical cord. In comparison, spinal AVMs have no gender predominance and tend to present between the ages of 20 and 60 years old. Just over half of spinal AVMs are found within the thoracic cord, almost a third are cervical and the remaining are in the lumbar spine.

Pathobiology

Frank hemorrhage is not necessary to cause many of the symptoms of spinal vascular malformations. In both DAVF and AVM, the abnormal direct arterial flow into the venous system may result in myelopathy via cord compression as well as via the development of venous hypertension, which leads to intramedullary edema. Additionally, in the setting of large arteriovenous lesions, vascular steal may occur, resulting in cord ischemia. Finally, symptoms may occur when arterial pressure overwhelms the accommodation of the venous wall, leading to hemorrhage; this is more common in AVM than DAVF.

Clinical Features

Chronically progressive motor deficits, especially paraparesis, are the most common presenting symptom. The weakness may worsen with exercise. Almost half of patients will have pain, often radicular, referable to the lesion. The diagnosis often eludes detection for years, although one clinical key may be the stepwise pattern of progression. Notably, in the case of AVMs, approximately half of patients present acutely with sudden onset of myelopathic symptoms due to hemorrhage.

Diagnosis

On standard MRI sequences, signs of AVM and DAVF include cord edema and enhancement. A T2-based MRI sequences may detect characteristic abnormal flow voids with sensitivity to detect small abnormalities increased by the addition of contrast. Magnetic resonance angiography with contrast enhancement can also aid in the detection of an AVM. However, if magnetic resonance is not diagnostic and clinical suspicion remains, conventional digital subtraction angiography remains the gold standard for diagnosis. It also has the added benefit of allowing for therapeutic intervention if the diagnosis is confirmed.

Management

Treatment options for AVM and DAVF include embolization of the feeding arteries, surgical clipping or resection, and gamma knife radiosurgery. Frequently, a combination of these treatment modalities is necessary. The treatment of asymptomatic and unruptured cranial lesions, especially AVM, is quite controversial. The A Randomized Multicenter Clinical Trial of Unruptured Brain AVMs (ARUBA) was stopped prematurely due to an increased rate of adverse events in the intervention arm—including all of these options—as compared to conservative medical therapy. Although this trial excluded spinal AVMs, these results should be considered.

Outcome

Prognosis can be difficult to predict; as may be expected, the patient's age, duration, and severity of myelopathic symptoms are critical variables that influence response to treatment. Overall, complete obliteration of the vascular lesion may be difficult to attain—especially with AVMs—however, in most cases, even partial treatment can result in significant clinical improvement.

FIGURE 115.3 Dural arteriovenous fistula. **A:** Sagittal T2-weighted image of the thoracic spine shows T2 hyperintensity in the thoracic spinal cord with tortuous flow voids *(arrow)* over the dorsal aspect of the cord. **B:** Sagittal maximum-intensity projection from time-resolved magnetic resonance angiogram shows enlarged veins filling during arterial phase of imaging *(arrow)* due to shunting in the fistula. **C:** Catheter angiogram with selective injection into a spinal segmental artery shows the fistula, with the same enlarged tortuous veins *(arrow)* at the surface of the spinal cord. (From Kranz PG, Amrhein TJ. Imaging approach to myelopathy: acute, subacute, and chronic. *Radiol Clin North Am.* 2019;57[2]:257-279.)

TOXIC/METABOLIC CAUSES OF MYELOPATHY

Numerous causes of toxic or metabolic myelopathy may present with similar progressive myelopathic symptoms. The specific diagnosis derives from a combination of history of past exposures, systemic manifestations, and laboratory testing. Nutritional deficiencies, especially those of cyanocobalamin, folate, vitamin E, and copper, are discussed extensively in Chapter 128.

Myelopathy due to Radiation or Chemotherapy

Radiation therapy and a number of medications, especially chemotherapeutics, have been reported to cause myelopathy. The risk of myelopathy as a consequence of radiation therapy increases nonlinearly with the dose of radiation, with a reported prevalence of approximately 5% of patients who receive 60 cGy to the spinal cord as compared to only 1% of patients who were treated with 50 cGy. Radiation-induced myelopathy commonly presents in one of two ways. The most common is a transient myelopathy presenting with Lhermitte phenomenon approximately 6 weeks to 6 months after radiation. The MRI is typically normal, and symptoms resolve over weeks to months. There is also a delayed presentation that is a chronic and progressive form of radiation-induced myelopathy. This presents months to years after radiation. There is no consensus on treatment, but corticosteroids, hyperbaric oxygen, bevacizumab, and anticoagulation have all been tried. Of the chemotherapeutics, methotrexate and cytarabine are the most frequent offenders and are most likely to lead to a myelopathy in those treated intrathecally or with systemic doses that are high enough to penetrate the blood-brain barrier. If chemotherapy-related myelopathy occurs, it generally does so within hours to weeks after treatment and usually after the patient has received multiple doses. A number of other chemotherapeutics have been reported to cause myelopathy including fludarabine, cladribine, thiotepa, doxorubicin, and daunorubicin. In addition, amphotericin B has been reported to contribute to development of myelopathy.

Nitrous Oxide Toxicity

Nitrous oxide (NO) is an inhaled anesthetic that is used primarily for dental procedures. Therefore, occupational exposure is a risk, although NO toxicity more frequently results from recreational abuse in the form of "whippets," derived from whipped cream canisters. The NO-induced myelopathy typically results relatively rapidly after abuse and is associated with functional vitamin B_{12} deficiency due to interference with vitamin B_{12} metabolism.

Accordingly, the clinical picture, with the exception of the rate of symptom onset, which is often much more rapid in the setting of NO abuse, is identical to subacute combined degeneration including prominent proprioceptive loss in addition to spastic paraparesis. If a patient is expected to undergo a procedure with NO anesthesia and has moderately low vitamin B_{12} levels, supplementation with cyanocobalamin for a few weeks prior to the procedure can prevent this complication.

Hepatic Myelopathy

Hepatic myelopathy is an uncommon and overlooked consequence of advanced cirrhosis. It is characterized by a spastic paraparesis that almost always spares the arms and which progresses slowly over years. Sensory and autonomic symptoms are typically absent. The myelopathy is often preceded by hepatic encephalopathy and most frequently occurs in the setting of a portosystemic shunt. The MRI is often normal, especially early in the disease; however, motor-evoked potentials may confirm an abnormality. The pathobiology is unknown. There is mixed literature on improvement after liver transplantation, with some suggesting that transplantation before symptoms become too severe may allow for some degree of recovery.

GENETIC CAUSES OF MYELOPATHY

The genetic causes of myelopathy include hereditary spastic paraplegia (HSP), motor neuron disease, disorders of metabolism, and spinocerebellar degeneration. Within this section, we focus primarily on HSP.

Hereditary Spastic Paraplegia

Epidemiology

An HSP is a heterogeneous group of neurodegenerative disorders associated with mutations in any of over 50 genes with usually either autosomal dominant or autosomal recessive inheritance. The HSP has a prevalence of 5.5 cases per 100,000. Among families with autosomal dominant inheritance, the most frequent culprit mutations occur in SPG4 followed by SPG3A. Among families with autosomal recessive inheritance, mutations within SPG11 are the most common, with SPG15 and SPG5 mutations as the second and third most common anomalies. X-linked and mitochondrial causes also exist, but the epidemiology of these is not as well studied. In addition, de novo mutations can occur in the absence of family history.

Pathobiology

An HSP is classically associated with axonal degeneration at the distal ends of the lateral corticospinal tracts, often accompanied by distal degeneration within the fasciculus gracilis as well. The molecular basis for these abnormalities varies widely depending on the particular causal gene, with abnormalities involving axonal and endosomal trafficking, endoplasmic reticulum morphogenesis, lipid metabolism, and mitochondrial regulation. Further information can be found in reviews by Fink as well as Noreau and colleagues.

Clinical Features

An HSP can present at any age. It typically begins as a gait abnormality due to impaired dorsiflexion secondary to extensor spasticity. Especially early in the disease, spasticity is a more prominent finding than actual weakness and may be mildly asymmetric. As the disease progresses, more proximal leg muscles become involved leading to a scissoring gait (adductor spasticity). Abnormalities of vibratory and position sense as well as bowel and bladder control may also be seen. The arms are generally spared except for possible hyperreflexia. "Complicated" HSP refers to cases with additional symptoms such as cognitive impairment, epilepsy, parkinsonism, ataxia, peripheral neuropathy, amyotrophy, or vision or hearing loss.

Diagnosis

A presumptive diagnosis of HSP is usually made based on a combination of personal and family history and physical exam. Genetic testing finds the causative gene in only 33% to 55% of autosomal dominantly inherited cases and 18% to 29% of autosomal recessively inherited cases. The MRI is often normal but may show distal spinal cord atrophy, especially later in disease course. Sensory-evoked potentials are often abnormal, even in patients without clinical evidence of sensory abnormalities.

Management

Treatment is symptomatic. Muscle relaxants such as baclofen, tizanidine, or diazepam may aid with spasticity. Botulinum toxin injection may prove helpful in more resistant cases. Physical therapy is always encouraged to help maintain range of motion and mobility. Symptoms of spastic bladder can be treated with anticholinergic medications such as oxybutynin.

Outcome

An HSP does not typically shorten life expectancy, and many patients will experience a plateau in neurologic decline after which the degree of disability seems to stabilize. At what point this plateau will occur, however, will vary by patient and is difficult to predict.

Autonomic Failure, Autonomic Neuropathy, and Orthostatic Intolerance 116

Louis H. Weimer

KEY POINTS

1. Autonomic manifestations are common in neurologic disease but are lesser concerns in many cases.
2. Diabetes is the most common cause of autonomic neuropathy.
3. Orthostatic intolerance/postural orthostatic tachycardia syndrome is the most common cause of autonomic symptoms and autonomic center visits.
4. Many causes of severe autonomic failure and hereditary neuropathy are known but most are quite rare.
5. Parkinson disease, pure autonomic failure, and multiple system atrophy are the most important degenerative causes of autonomic failure.

INTRODUCTION

Autonomic disorders are generally considered to be uncommon conditions, but in fact, autonomic dysfunction is ubiquitous in neurologic disease, including highly prevalent processes such as seizures, strokes, mass lesions, infections, multiple sclerosis plaques, and others, but dysautonomia is often a secondary concern. A limited number of disorders produce severe or isolated dysautonomia or autonomic failure (AF). Figure 116.1 displays a representation of the most prominent or most important causes. The conditions span all anatomic and most pathologic neurologic domains. Because autonomic systems affect virtually all organ systems, symptoms produced are multiple and varied, often affecting functions not considered by most neurologists. Problems can arise from any site of autonomic control including the central cortical and subcortical autonomic network, brainstem, spinal cord, autonomic ganglia, or peripheral autonomic nerves. The range of pathogenic mechanisms is highly varied, including degenerative, hereditary, immune-mediated, paraneoplastic, aberrant reflex, and metabolic, among others. Suspicion of autonomic dysfunction rests with the clinician and can be missed if symptoms that can appear to be nonspecific are considered in isolation (Table 116.1). Early symptoms of the most characteristic finding, orthostatic hypotension (OH), may appear as postural fatigue, cognitive change, anxiety, or vertigo. This lack of certainty in many cases makes more objective assessment desirable in these instances (see Chapter 28).

EPIDEMIOLOGY

Postural hypotension (OH) is a prevalent clinical sign seen in numerous and diverse neurologic and nonneurologic conditions. Shibao et al estimated over 80,000 U.S. OH-related hospitalizations in 2004; OH was the primary diagnosis in 35%. One consensus agreement defines OH as a fall in systolic blood pressure (BP) of 20 or 10 mm Hg diastolic within 3 minutes of standing or similar orthostatic challenge, such as upright tilt, although some require a 30 mm Hg decline. OH, however, may be asymptomatic, especially in the elderly, and varies according to underlying conditions or confounding factors (Table 116.2). The sign is one marker of advanced AF caused by either diseases of central autonomic pathways or autonomic neuropathy. Some severe and important causes are discussed; a more comprehensive list is provided in Table 116.3. Acute and subacute processes are generally considered separately from more chronic conditions.

ACUTE AND SUBACUTE AUTONOMIC DISORDERS

Acute or subacute autoimmune autonomic neuropathy (AAN) or acute pandysautonomia is an unusual but distinct entity, which primarily affects peripheral autonomic nerves. Roughly, half are preceded by a viral prodrome similar to Guillain-Barré syndrome. Patients typically develop generalized AF including OH, anhidrosis, parasympathetic failure, and gastrointestinal dysfunction, although predominantly adrenergic and cholinergic variants are seen. The illness is monophasic with acute or subacute onset over several weeks. Recovery generally occurs but is often slow and incomplete. Acute signs such as ileus may develop into lesser degrees of gastrointestinal dysmotility including bloating, early satiety, nausea, vomiting, and alternating diarrhea and constipation. Antecedent viruses include herpes simplex, mononucleosis, rubella, and nondescript febrile illnesses. Roughly 25% have a restricted cholinergic form (acute cholinergic neuropathy)

FIGURE 116.1 Schematic representation of neurogenic orthostatic hypotension causes based on disease localization. Abbreviations: AAG, autoimmune autonomic ganglionopathy; AAN, autoimmune autonomic neuropathy; ADLD, autosomal dominant leukodystrophy; CRF, chronic renal failure; DBH, dopamine-β-hydroxylase; DM, diabetes mellitus; FD, familial dysautonomia (hereditary sensory and autonomic neuropathy type III, Riley-Day syndrome); LBD, Lewy body dementia; MS, multiple sclerosis; MSA, multiple system atrophy; PAF, pure autonomic failure; PD, Parkinson disease. (From Eschlböck S, Wenning G, Fanciulli A. Evidence-based treatment of neurogenic orthostatic hypotension and related symptoms. *J Neural Transm [Vienna]*. 2017;124:1567-1605.)

TABLE 116.1 Autonomic Review of Symptoms

• Secretomotor: dry eyes and mouth, often required natural tears or frequent sips of water. Excessive saliva can also occur.
• Orthostatic: dizziness, weakness, fatigue, cognitive changes, visual disturbance, vertigo, anxiety, palpitations, pallor, nausea, syncope
• Postprandial: bloating, fullness, nausea, dizziness, sweating, orthostatic hypotension
• GI: constipation, nocturnal or intermittent diarrhea
• GU: urinary retention, difficulty with initiation, incomplete emptying, incontinence
• Sexual: erectile failure, ejaculatory dysfunction, retrograde ejaculation into bladder
• Visual: blurred vision, sensitivity to light/glare, reduced night vision
• Sudomotor: reduced loss of sweating ability (distally in polyneuropathies); excessive, paroxysmal, or inappropriate sweating; mixed pattern of loss and excessive areas, heat intolerance
• Vasomotor: distal color changes, change in skin appearance, persistently cold extremities, Raynaud phenomenon, loss of skin wrinkling in water, heat intolerance
• Other: unexplained syncope

Abbreviations: GI, gastrointestinal; GU, genitourinary.

TABLE 116.2 Factors Affecting Orthostatic Hypotension

Aggravating Factors
• Warm environment, hot bath
• Postexercise
• Prolonged motionless standing
• Large meals (carbohydrate load)
• Early morning
• Valsalva maneuver, isometric exercise
• Standing after squatting
• Volume depletion
• Rising after prolonged bed rest
• Rapid postural change
• Space flight
• Alcohol
• Medications
Beneficial Maneuvers
• Squatting, leg crossing
• Abdominal and leg compression
• Nighttime slight upright tilt
• Isotonic exercise

TABLE 116.3 Selected Disorders of Autonomic Function

Isolated Degenerative Autonomic
PAF, "Bradbury-Eggleston syndrome"
Multisystem Degenerative Disorders
MSA
Parkinson disease with autonomic failure
Central
Brain tumors (posterior fossa, third ventricle, hypothalamus), syringobulbia, MS, tetanus, Wernicke-Korsakoff syndrome, fatal familial insomnia
Spinal Cord
MS, syringomyelia, transverse myelitis, trauma, mass lesion
Peripheral
Immune mediated
Guillain-Barré syndrome (see Chapter 91), acute and subacute autonomic neuropathy, acute cholinergic neuropathy, Sjögren disease, SLE, rheumatoid arthritis, Holmes-Adie syndrome, Ross syndrome, Harlequin syndrome, acute anhidrosis
Metabolic
Diabetes, vitamin B_{12} and thiamine deficiency, uremia
Paraneoplastic
Paraneoplastic autonomic neuropathy and paraneoplastic syndromes with autonomic neuropathy (ANNA-1, α3-AchR ganglionic, CRMP5, PCA-2 antibodies), enteric neuropathy, Lambert-Eaton myasthenic syndrome (cholinergic)
Infectious
Chagas disease (cholinergic), syphilis, leprosy, HIV, Lyme disease, diphtheria
Hereditary
Familial amyloidosis, hereditary sensory and autonomic neuropathies (see Chapter 92), dopamine β-hydroxylase deficiency, porphyria, Fabry disease, norepinephrine transporter deficiency, fragile X premutation–associated tremor/ataxia syndrome, CANVAS syndrome, Hirschsprung megacolon, Ehlers-Danlos type III, myopathy, external ophthalmoplegia, neuropathy, gastrointestinal encephalopathy (MNGIE), Machado-Joseph disease, prion-induced diarrhea, and autonomic neuropathy
Toxins and Medications
Botulism, vincristine, cisplatin, taxoids, amiodarone, pyriminil (Vacor), hexacarbon, carbon disulfide, heavy metals, podophyllin, alcohol, PD-1 inhibitors
Drug and Medication Effects
Anticholinergics: tricyclic antidepressants, atropine, oxybutynin
β-Adrenergic blockers: propranolol and others
α_2-Agonists: clonidine, prazosin, α-methyl dopa, terazosin, doxazosin
α_1-Antagonists: phentolamine, phenoxybenzamine, guanabenz
Ganglionic blockers: guanethidine, hexamethonium, mecamylamine
Others: hydralazine, nitrates, diuretics, calcium channel blockers, ACE inhibitors, antihistamines, antipsychotics, Sinemet, narcotics, sildenafil, tadalafil
Reduced orthostatic tolerance
Neurocardiogenic syncope, POTS, mitral valve prolapse syndrome, prolonged bed rest or weightlessness, Chiari malformation
Others
Acquired amyloidosis, chronic idiopathic autonomic neuropathies, small-fiber neuropathy, idiopathic hyperhidrosis, idiopathic anhidrosis, Horner syndrome

Abbreviations: ACE, angiotensin-converting enzyme; AchR, acetylcholine receptor; ANNA-1, type 1 antineuronal nuclear antibodies; CANVAS, cerebellar ataxia, neuropathy, vestibular areflexia syndrome; CRMP5, collapsin response mediator protein 5; HIV, human immunodeficiency virus; MNGIE, mitochondrial neurogastrointestinal encephalomyopathy; MS, multiple sclerosis; MSA, multiple system atrophy; PAF, pure autonomic failure; PCA-2, Purkinje cell cytoplasmic antibody type 2; PD-1, programmed cell death protein 1; POTS, postural orthostatic tachycardia syndrome; SLE, systemic lupus erythematosus.

characterized by dry eyes and mouth, gastrointestinal dysmotility, bladder dysfunction, hypohidrosis, unreactive pupils, fixed heart rate, and sexual dysfunction but without significant OH. Abnormalities on formal autonomic testing are prominent in the involved systems. Nerve conduction studies are typically normal or show minor sensory abnormalities. The lack of OH in cholinergic cases complicates the diagnosis.

Demonstration of high-titer antibodies to nicotinic ganglionic acetylcholine receptor (AChR) α-3 subunits, which are similar but distinct from those at the neuromuscular junction (α-1 subunits), supports an immune-mediated basis. A paraneoplastic form, which develops in a similar time course and is indistinguishable on clinical or laboratory grounds, may appear prior to tumor discovery, most commonly thymoma. In screening patients with autonomic disorders and controls, Vernino et al found that 41% of patients with idiopathic autonomic neuropathy had high antibody titers; paraneoplastic neuropathy patients were frequently positive as well. Rarely, patients with chronic OH and AF have high antibody titers and respond to immunotherapy, such as intravenous immunoglobulin or plasma exchange. Some patients with orthostatic intolerance, discussed later, and idiopathic gastrointestinal dysmotility, but none with chronic degenerative autonomic processes, also had positive assays at lower titers. Knockout mouse models of the α-3 subunit gene, rabbits immunized against the subunit, and passive antibody transfer to other animals all induce signs of AF supporting the assertion that the antibodies are causative. Antibody titers also correlate with disease severity. Of note, low-level titers may occur in patients with other disorders or nonspecific symptoms. One-third of AAN patients recover, one-third have a partial recovery with substantial deficits, and the remainder do not improve. Gastrointestinal dysfunction and OH are usually the most debilitating manifestations. Supportive care and management of the OH and system-specific problems are the mainstays of treatment. Rare cases with AAN and myasthenia gravis have both types of AChR antibodies. Autonomic involvement is common in typical Guillain-Barré syndrome, discussed in Chapter 91, especially in more severe cases, and is a prominent cause of morbidity and mortality.

Paraneoplastic Autonomic Neuropathy

Subacute autonomic neuropathy or predominantly enteric neuropathy is also seen in isolation or with somatic sensory neuropathy and other underlying antibodies, especially type 1 antineuronal nuclear antibodies (ANNA-1; anti-Hu) usually in patients with small cell lung cancer. Paraneoplastic neuropathy is also associated with other paraneoplastic antibodies including

Purkinje cell cytoplasmic antibody type 2 (PCA-2) and collapsin response mediator protein-5. Botulism (cholinergic), acute intermittent porphyria, and toxic neuropathy are other diagnostic considerations. A rare chronic form associated with high titers to ganglionic antibodies is known that can mimic degenerative AF. Autonomic manifestations are also common in patients with Lambert-Eaton myasthenic syndrome, especially cholinergic complaints and manifestations (see Chapter 93).

Orthostatic Intolerance

Exaggerated orthostatic tachycardia may be evident in some cases without significant cardiac denervation. This led to the proposal that some patients with the common syndrome of idiopathic orthostatic intolerance without OH (postural orthostatic tachycardia syndrome), also known as *orthostatic intolerance*, may have an attenuated form of acute autonomic neuropathy. This syndrome without or without neuropathic signs is extremely common and increasingly appreciated. Orthostatic intolerance symptoms include postural light-headedness, fatigue, cognitive changes, and presyncope despite minimal changes in BP. Potential mechanisms are multiple, including excessive venous pooling, idiopathic hypovolemia, and adrenergic hypersensitivity. A minority have signs of autonomic neuropathy supported by abnormalities of sudomotor and other autonomic systems in one-third of cases and an overrepresentation of antecedent viral infection in these patients. However, the majority of cases are idiopathic. The common physiologic thread is presumed bouts of cerebral hypoperfusion, despite a seemingly adequate systemic BP, but BP is often in the low range of normal. This syndrome is the most common cause of consultation in most autonomic centers—the prevalence is estimated to be from 1 to 4 million cases in the United States. The condition is much more common in women, roughly 5:1 and commonly initially develops between ages 15 and 25 years, often after an acute illness, such as a viral syndrome. Other cases are lifelong often starting in early teen years. Postural orthostatic tachycardia syndrome/orthostatic intolerance is not associated with mortality, but sharply reduced quality life scores and increased suicide rates are reported. An association with joint hypermobility and presumed or documented Ehlers-Danlos syndrome type III is recognized. Patients with grade I Chiari malformations also typically have multiple autonomic symptoms, including orthostatic intolerance. Roughly, 40% of patients have additional vasovagal syncopal episodes. The condition must be distinguished from depression, vestibular disorders, chronic fatigue, fibromyalgia, and panic disorders but many overlap cases exist; many patients have coincident chronic and not postural fatigue, insomnia, and chronic pain. Uncommon symptomatic causes must be considered, such as adrenal insufficiency, pheochromocytoma, celiac disease, and Sjögren syndrome. Elimination of cardiac causes is also critical, notably supraventricular tachycardia. Mast cell activation disorder is a common association. The syndrome often leads to secondary deconditioning, which complicates recovery. An indistinguishable hereditary form resulting from a mutation in a norepinephrine transporter gene is known but is exceedingly rare. Similar symptoms can be seen in patients with predominantly painful small fiber neuropathy due to additional involvement of distal autonomic nerves. Treatment must be individualized based on the most prominent symptoms but is generally based on improving standing BP, increasing blood volume, minimizing anemia, and increasing activity levels. Some exercise regimens are promoted but nonupright exercise is typically best tolerated. Increased water and increased dietary salt or salt supplements are typically initially tried. If insufficient, BP raising measures can improve function; however, hypertension should be avoided. Medication options include fludrocortisone, 0.05 to 0.2 mg/d; midodrine 2.5 to 10 mg 3 times a day but not after 6 PM; and pyridostigmine, 30 to 60 mg 3 times a day. However, none of these treatments has been rigorously studied. Caffeine and stimulations help a minority, but many patients are highly intolerant to agents that increase heart rate. Beta blockade is helpful in patients with bothersome palpitations and hyperadrenergic forms but is counterproductive in other subtypes. Recovery is often very slow and incomplete. Immune-mediated treatment for this multifactorial syndrome remains controversial.

CHRONIC NEUROGENIC ORTHOSTATIC HYPOTENSION AND AUTONOMIC NEUROPATHY

Parkinsonian Syndromes and Pure Autonomic Failure

Marked AF in patients with multiple system atrophy (MSA), especially the former Shy-Drager syndrome, is frequent. Other autonomic symptoms often predate OH, including impotence, decreased sweating, and urinary incontinence. MSA is a group of disorders with overlapping neuropathology and may have autonomic, parkinsonian, or cerebellar symptoms at onset or later, as discussed in Chapter 87. Other common manifestations include sleep apnea, incontinence, impotence, dystonia, inspiratory stridor, hoarseness, lack of rest tremor, and ineffective or transient L-dopa response. Virtually all MSA patients eventually show autonomic signs or symptoms, regardless of initial manifestations. Demonstration of argyrophilic glial cytoplasmic inclusions in oligodendroglia is a characteristic but not a pathognomonic MSA hallmark. Glial cytoplasmic inclusions are prominent in sites of central autonomic control and correlate better with clinical findings than do areas of neuronal loss. Consensus diagnostic criteria first published in 1996 were simplified and refined in 2008. Increased risk of MSA has been found in families and some sporadic cases from various mutations in the gene COQ2, which is essential for the biosynthesis of coenzyme Q10. Median survival from symptom onset is approximately 10 years based on the most recent natural history studies; parkinsonism at onset and incomplete bladder emptying were the most predictive factors for faster progression.

Many patients with idiopathic Parkinson disease (IPD) also have autonomically mediated complaints, most commonly constipation and urinary dysfunction, but measurable OH is often asymptomatic. However, the prevalence of autonomic symptoms in IPD patients is well recognized. Exacerbation or inducement of OH from medications such as L-dopa is recognized and variably clinically significant.

Some patients with otherwise typical IPD have more severe AF including symptomatic OH and are designated Parkinson disease with AF. A separate disorder known as *pure autonomic failure* (PAF) or idiopathic OH, first described by Bradbury and Eggleston in 1925, is a profound, slowly progressive disorder with disabling OH, usually starting after age 50 years. By definition, no other neurologic impairment is seen, and the ultimate

diagnosis is often delayed 3 to 5 years to ensure that MSA or parkinsonism does not emerge. Autopsies show a similar pattern of classic Lewy bodies in peripheral autonomic and enteric ganglia in both Parkinson disease with AF and PAF. Similarities between these Lewy body disorders are further supported by cardiac fluorodopamine positron emission tomography studies demonstrating loss of cardiac sympathetic innervation in both conditions but not in MSA patients. The shared neurodegenerative mechanisms between IPD, diffuse Lewy body dementia, and PAF is recognized.

Dopamine β-hydroxylase deficiency is a very rare but treatable entity with severe OH, syncope, and nearly undetectable norepinephrine and epinephrine leading to a failure of BP maintenance while standing. The norepinephrine precursor (droxidopa), is beneficial for these patients and in patients with other forms of AF, was U.S. Food and Drug Administration (FDA)-approved in 2014, commonly titrated to a target dose of 100 to 600 mg three times a day.

Cerebellar ataxia, neuropathy, and vestibular areflexia syndrome is a recognized neurodegenerative ganglionopathy that commonly includes OH; in one series, 83% had evidence of autonomic dysfunction.

Numerous other common and uncommon disorders affecting the brain and spinal cord affect autonomic function but less commonly cause symptomatic OH (see **Table 116.3**). Additionally, some processes may be pathway- or organ-specific such as predominantly cholinergic, adrenergic, regional, or organ-specific disorders. Anhidrosis or hypohidrosis occurs with a variety of process, notably in length-dependent neuropathy. Regional and segmental hypohidrosis can occur; when associated with Adie pupils and hyporeflexia, the condition is known as *Ross syndrome*; some cases occur following viral infection and are presumed to be immune-mediated. Acute or subacute generalized anhidrosis also occurs. Patients, however, more commonly note increased sweating. Compensatory proximal sweating is common in patients with large areas of reduced sweating from any cause. Essential hyperhidrosis is diffuse tendency for excessive sweating and is often hereditary. Treatments directed at reducing sweating include traumatizing sweat glands with water iontophoresis, chemodenervation, or strong antiperspirants; simple anticholinergic medications are typically ineffective at tolerable dosage. Surgical endoscopic sympathectomy is an option for severe cases.

Chronic Autonomic Neuropathies

Many of the scores of different peripheral neuropathies induce autonomic dysfunction, often limited to distal sweating and vasomotor control, especially those disproportionately affecting small-diameter fibers. The consequence is dry, cool distal extremities common in many neuropathy patients. Dysfunction is generally insufficient to impair peripheral vasoconstriction or postural reflexes enough to produce symptomatic OH. A few entities, however, lead to severe or targeted autonomic dysfunction, which can produce frank AF and symptomatic OH. Particularly noteworthy causes include diabetes; familial and acquired amyloidosis; paraneoplastic neuropathies; and selected hereditary, infectious, and toxic neuropathies. Some of the more prominent examples are listed in **Table 116.3**.

Diabetic autonomic neuropathy (DAN) is the most common and important cause of autonomic neuropathy and the most extensively examined. Somatic peripheral neuropathy is usually concurrent. Much attention has focused on the impact of diabetic autonomic dysfunction on long-term survival. Ewing et al found 56% of 73 patients with DAN died within 5 years, many owing to nonautonomic complications such as renal failure. Later studies showed an increased but less ominous DAN mortality rate in diabetics without other initial complications (23% at 8 y) compared with diabetics without DAN and similar disease duration (3% at 8 y). The added autonomic dysfunction risk is independent of coronary perfusion deficits. Upper gastrointestinal dysmotility, bladder complaints, impotence, sudomotor loss, constipation, episodic diarrhea, and gustatory sweating are a few common manifestations that aid in diagnosis and may require symptomatic treatment.

Amyloidosis, including both hereditary and acquired forms, is another important consideration in patients with severe AF. Acquired forms are typically neoplastic and treated primarily by oncologists by chemotherapy and often bone marrow and stem cell transplantation. Hereditary forms are typically discovered by cardiologists or neurologists. Certain mutations in transthyretin are associated with more severe autonomic neuropathy than other mutations; approximately 130 different mutations are known. Some forms commonly cause neuropathy, whereas others rarely do; the Val30Met or common mutation is particularly significant. Patisiran, an RNA interfering molecule, and inotersen, an antisense oligonucleotide, are highly effective treatments now approved by the FDA for treatment of hereditary familial amyloid polyneuropathy. Tafamidis was approved in 2019 for familial amyloid cardiomyopathy but may help autonomic aspects as well. Other treatments remain in the pipeline. Patisiran was shown to significantly improve autonomic symptoms compared to placebo at the 18-month APOLLO trial assessment. Notably, treated patients showed stable or improved autonomic symptoms, whereas placebo patients notably declined.

Immune-mediated and paraneoplastic neuropathy are potentially treatable and often begin subacutely. A chronic form is also seen in isolation or in association with other autoimmune disorders, notably Sjögren disease. A notable report in 2005 complicated diagnosis by demonstrating a patient with presumed, very long-standing, stable AF, who demonstrated high AChR ganglionic antibodies, typically reserved for acute and subacute neuropathy, and responded markedly and repeatedly to recurrent intravenous immunoglobulin infusions.

Idiopathic painful, small-fiber neuropathy often affects distal autonomic function but rarely causes symptomatic OH or symptomatic AF. Other forms of autonomic neuropathy are listed in **Table 116.3**.

DIAGNOSIS AND MANAGEMENT OF AUTONOMIC DISORDERS

Nonautonomic conditions can cause OH and mimic AF; most important are adrenal failure and pheochromocytoma. Asymptomatic OH is a prevalent sign in the elderly, and causes are often multifactorial. Formal laboratory evaluation of autonomic disorders is discussed in Chapter 28.

Treatment of AF is directed at symptomatic relief, reduced syncope and fall risk, and improved quality of life, especially for generally the most disabling symptom—OH. Numerous pharmacologic and nonpharmacologic interventions are available

to lessen OH and improve orthostatic tolerance. Asymptomatic hypotension on standing usually requires no treatment; reasonable precautions and avoidance of precipitating factors may be adequate. An exercise reflex, which immediately but transiently lowers BP on standing may become symptomatic requiring standing slowly and in stages. However, lesser indicators of hypoperfusion such as postural "coat hanger" pattern shoulder fatigue and headache (local muscle ischemia), pure postural vertigo, postprandial fatigue, and cognitive slowing are possible indicators of OH. Supplemental water and salt intake (0.5-2 g/d) have been independently shown to be beneficial and lessen the need for medications. Raising the head of the bed 4 inches stimulates baroreceptors and decreases nocturnal diuresis. Useful postural and physical measures to attempt and others to avoid are listed in **Table 116.2**. Cumbersome compressive garments with abdominal compression are mildly effective in reducing venous pooling but are problematic for many with neurologic disorders; abdominal binders alone may help to a lesser degree. Small, frequent meals low in carbohydrates lessen postprandial hypotension. Reevaluation of the need for prescribed BP lowering and autonomically active agents should be considered. However, the evidence-based proof supporting these nonmedication efforts is weak.

If these measures are insufficient, first-line medications include fludrocortisone (starting at 0.1 mg/d) or the α-adrenergic agonist midodrine or both. Midodrine is shorter acting, and the dosage must cover vulnerable periods, especially early morning, and is not given after 6 PM; generally 2.5 to 10 mg doses 3 times a day. Droxidopa was FDA approved in 2014 and may become an additional treatment option commonly titrated to a target dose of 100 to 600 mg 3 times a day. Excessive fluid retention and heart failure are concerns, especially in the elderly. Relative anemia exacerbates OH. Pyridostigmine, which enhances autonomic ganglionic neural transmission, increases standing greater than supine BP and is a common off-label option, especially in patients with supine hypertension, which is a perennial and unresolved controversial concern with fludrocortisone, midodrine, and droxidopa. Typically, 30 or 60 mg doses are given every 6 to 8 hours. Clinical judgment is required to balance the need for adequate standing and reasonable supine pressures; this balance is challenging in severe cases. Second-line agents are numerous and are sometimes effective if earlier agents have failed. Concomitant treatment of urinary dysfunction, gastric and intestinal dysmotility, impotence, and secretomotor dysfunction is often necessary. In MSA, inspiratory stridor may lead to tracheostomy, and nocturnal positive pressure ventilation may be needed for sleep apnea.

Eschlböck and colleagues preformed an evidence-based review of neurogenic orthostatic and postprandial hypotension treatments based on the Grading of Recommendations Assessment, Development, and Evaluation methodology. Fluids, maneuvers, compression treatments, and medications were considered based on all available published studies. Efficacy, side effects, and safety are included in the recommendation that makes some conclusions controversial. The level of evidence was strong and recommendation high for midodrine. Evidence is moderate for droxidopa but recommendation was strong. These two agents are currently the only ones FDA approved to treat neurogenic OH. Partly because no dedicated modern studies are available, the evidence was weak and resultant recommendation was low for fludrocortisone. The strongest evidence for a nonmedication was for an abdominal binder.

Exacerbating factors are important considerations for both patient and physician to take appropriate precautions or avoid certain situations (see **Table 116.2**). Patients with delayed OH (3-15 min after standing) or situational triggers must anticipate potential problems. Patients with chronic, symptomatic OH may learn to recognize these conditions but often need physician instruction. Chronic OH also results in optimized cerebral autoregulation and relative tolerance of low BP but provides a narrow window between an asymptomatic state and syncope.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHY AND FAMILIAL DYSAUTONOMIA

The onset of some autonomic disorders occurs much earlier than those already discussed, including some congenital and infantile hereditary conditions. The most common and important entities are discussed.

Familial Dysautonomia (Riley-Day Syndrome)

Hereditary sensory and autonomic neuropathy type III, also known as *familial dysautonomia* (FD) and was first described by Riley et al in 1949, is a rare autosomal recessive disease with complete penetrance but variable expression. Virtually all patients are of eastern European (Ashkenazi) Jewish descent. The carrier rate may be as high as 1 in 25, and the disease prevalence was 1 in 4,100 live births. However, following the availability of genetic testing, subsequent to the gene discovery in 2001, the incidence sharply dropped. In 2009, only five new FD cases were diagnosed worldwide. There is no sex predilection in either affected individuals or carriers. The condition affects the survival and development of sensory, sympathetic, and some parasympathetic neurons. Autonomic symptoms are prominent, and general somatic growth is affected.

The causative gene is ELP1 (elongator complex protein 1), previously named IKBKAP (I kappa B kinase complex–associated protein). Two mutations in the ELP1 gene are implicated. The major FD mutation is a splice defect that displays tissue-specific expression and causes aberrant mRNA splicing. The second more infrequent mutation is a missense mutation. The end result is a nonfunctional protein and a congenital sensory and autonomic neuropathy. Specific assay for mutations of IKBKAP/ELP1 have facilitated carrier screening for FD in the Ashkenazi Jewish population. Prenatal diagnosis is available, and preimplantation genetic diagnosis is also available for at-risk couples.

The condition can be identified in the neonatal period; clinical manifestations tend to increase with age. FD is currently classified as hereditary sensory and autonomic neuropathy type III.

Clinical Manifestations

Neurologic abnormalities detected in the neonatal period include decreased muscle tone, diminished or absent deep tendon reflexes, absent corneal responses, reduced Moro reflex, and weak cry and suck. The tongue tip lacks fungiform papillae and appears smooth. Uncoordinated swallowing with resultant regurgitation may cause aspiration and pneumonia. Some infants require tube feeding, gastrostomy, and fundoplication because of gastroesophageal reflux. Absence of overflow tears, which can

be normal for the first 3 months, persists and becomes a consistent feature. Corneal ulceration can occur.

During the first 3 years of life, affected children show delayed physical and developmental milestones, episodic vomiting, excessive sweating, excessive drooling, blotchy erythema, and breath-holding spells. Up to one-third of patients have seizures during early life, usually associated with fever or hypoxia. Less than 10% of patients have subsequent epilepsy. Dysautonomic crises occur usually after age 3 years characterized by irritability, self-mutilation, negativistic behavior, diaphoresis, tachycardia, hypertension, and thermal instability; however, episodes share many characteristics of autonomic seizures and typically respond to anticonvulsants. Episodic vomiting is frequent and can be cyclic, requiring hospitalization for stabilization with parenteral hydration and sedation.

School-aged patients tend to have short stature, awkward gait, and nasal speech. School performance may be poor, frequently 20 or more intelligence points below unaffected siblings. Scoliosis is frequent. Adults older than age 20 years often have spinal deformity. Vomiting and dysautonomic crises tend to decrease during adolescence when more frequent symptoms center on decreased exercise tolerance, poor general coordination, emotional difficulties, and postural hypotension. Vasovagal syncope may occur randomly, after micturition, or during laryngeal intubation for anesthesia.

There is a high incidence of sudden death, syncope, electrocardiographic abnormalities including asystole, bradycardia, atrioventricular block, and prolonged QT interval. Pacemaker placement to protect FD patients has not been found to be protective against fatal bradyarrhythmias but may decrease syncope incidence.

Diagnosis

The diagnosis should be suspected because of the specific clinical symptoms and findings and the familial Ashkenazi Jewish background. The FD gene test provides definitive confirmation. DNA diagnoses and genetic screening of the Ashkenazi Jewish population is available. If both parents are carriers, prenatal diagnosis can be done by chorionic villus sampling (10th-11th gestational week) or by amniocentesis (14th-17th gestational week). Preimplantation diagnosis is available for at-risk couples who would not consider pregnancy termination.

The intradermal histamine phosphate test can provide additional diagnostic confirmation. An intradermal injection of 1:1,000 histamine phosphate (0.03-0.05 mL) normally produces pain and erythema. A central wheel forms within minutes and is surrounded by an axon flare that is a zone of erythema measuring 2 to 6 cm in diameter. The flare lasts for several minutes. In dysautonomic patients, the pain is greatly reduced and there is no axon flare. In infants, a saline solution of 1:10,000 histamine should be substituted.

Biochemical and Pathologic Data

The protein product is part of a six-protein elongator complex, termed *IKAP*. The mutation decreases IKAP protein production, and treatments that increase the level of the full-length IKBKAP transcript are likely to have therapeutic value. Plasma levels of both norepinephrine and dopamine are markedly elevated during dysautonomic crises.

Pathologic data reveal hypoplastic cervical sympathetic ganglia with diminished volume and neuronal counts. Sympathetic preganglionic spinal cord neurons seem reduced in number and size. Patients are deficient in nonmyelinated and small-fiber neurons. Lingual submucosal neurons and sensory axons are reduced. Taste buds are scant; circumvallate papillae are hypoplastic.

Treatment

Preventative treatment and supportive therapies include maintaining eye moisture to control absence of tearing, fundoplication with gastrostomy to control vomiting and reflux, and the use of benzodiazepine and clonidine for dysautonomic crises.

The use of epidural or deep conscious sedation forms of anesthesia have been advocated for surgical procedures to avoid intubation and the sometimes fatal complications of general anesthesia.

OH is treated similarly to adult forms. Symptomatic treatment is indicated for dysautonomic crises with parenteral fluids, diazepam, sedation, and antiemetic therapy. Growth hormone treatment in selected patients with FD may have the potential to increase growth.

Tocotrienols may elevate IKBKAP gene expression and cause increased functional cellular levels of IKAP protein and increased levels of monoamine oxidase A in cells and tissues. Phosphatidylserine, a food supplement, and pridopidine elevate IKAP levels in cells generated from FD patients and may have therapeutic value. Other agents that correct the splicing defect are under investigation to increase functional protein levels. Postnatal correction of the splicing defect in an FD mouse model, using a small molecule kinetin, improved mouse proprioceptive function.

Outcome

Long-term survival is documented; more than 40% of surviving patients are older than 20 years. Some women with FD have had pregnancies and delivered normal infants. Infant and childhood fatalities may be a result of aspiration pneumonia, gastric hemorrhage, or dehydration. A second cluster of fatalities between the ages of 14 and 24 years has been secondary to pulmonary complications, sleep deaths, and cardiopulmonary arrests. The few oldest patients are now in their fifth and sixth decades.

Other Hereditary Autonomic Disorders

A novel prion disease associated with diarrhea and hereditary sensory and autonomic neuropathy associated with a defect in the PRNP gene was described late in 2013. Other types of hereditary sensory and autonomic neuropathy or often simply hereditary sensory neuropathy typically cause more severe sensory ganglionopathy or sensory neuropathy and are often considered as a separate congenital category.

ACKNOWLEDGMENT

The author acknowledges Dr. Alan M. Aron for contributions to an earlier version of the hereditary autonomic disorder section of this chapter.

117 Paroxysmal Sympathetic Hyperactivity After Acute Brain Injury

Sophie Samuel and Huimahn Alex Choi

KEY POINTS

1. Paroxysmal sympathetic hyperactivity (PSH) is a syndrome associated with episodes of increased sympathetic hyperactivity after acute brain injury.
2. PSH is characterized by sudden onset of transient symptoms characterized by hyperthermia, tachycardia, tachypnea, diaphoresis, and motor posturing.
3. The primary disturbance is a disconnection between inhibitory cortical pathways and autonomic nervous system centers in brainstem.
4. PSH is a diagnosis of exclusion.

INTRODUCTION

Paroxysmal sympathetic hyperactivity (PSH) is a syndrome of episodic physiologic hyperactivation manifesting in fevers, diaphoresis, tachycardia, tachypnea, hypertension, and dystonic posturing. The syndrome was first described in 1929, Wilder Penfield identified this phenomenon as diencephalic seizure because it was believed to be epileptic in nature. Since then, without a clear consensus definition, the syndrome has been described by many names: episodic autonomic instability, dysautonomia, autonomic dysregulation, central autonomic dysfunction, paroxysmal autonomic instability with dystonia, sympathetic storming, autonomic storming, dysautonomic crises. In 2014, the International Brain Injury Association developed a conceptual definition and created a census set of diagnostic criteria for this entity and proposed PSH as the name of this syndrome.

PSH is a poorly understood phenomenon, but it is widely accepted as a result of disconnection within the excitatory-to-inhibitory ratio (EIR) model. Identifying patients with these symptoms are often difficult. PSH is a diagnosis of exclusion, where other conditions with similar symptoms must first be ruled out. PSH can develop abruptly and last a short duration but can also be very challenging to manage if presenting with persistent symptoms. Delayed recognition can lead to unnecessary workup and administration of medications. This will further prolong hospitalization with potentially harmful results to patients. Additionally, uncontrolled symptoms can lead to multiorgan dysfunction secondary to brain injury.

EPIDEMIOLOGY

For decades, the absence of a unified diagnostic criterion, the unclear etiology, and the multiple different causes of PSH have hindered the study of the syndrome and resulted in widely differing estimates of prevalence of PSH from 7.7% to 33% in patients admitted to the intensive care unit, reflecting the differences in population of patients, diagnostic criteria, and time of diagnosis. The recently proposed diagnostic framework is an attempt to standardize the approach and aid in accurate and timely diagnosis of PSH.

The syndrome can manifest in both children and adults and can affect any age group and gender. The main risk factor for developing PSH after acute brain injury depends on the severity of the initial brain injury, younger age, and male gender. Few conditions predispose to the development of PSH, the most common being traumatic brain injury (79.4%), followed by hypoxic brain injury (9.7%), and stroke (5.4%). Although, traumatic brain injury may be the etiology for most cases of PSH, patients with other diseases may actually be at a higher risk for PSH. For instance, N-methyl-D-aspartate receptor–associated encephalitis is characterized by an aggressive and difficult to treat PSH-like syndrome.

PATHOBIOLOGY

The initial theory that the syndrome is epileptic in nature has been shown to be inconsistent with clinical and experimental evidence. Most believe PSH is caused by a functional disconnection leading to unbalanced activation of brainstem systems controlling the autonomic nervous system. Brain regions implicated range from the cerebral cortex to the anterior hypothalamus to the medulla and the connections in between. Regardless of the lesion location, the final common pathway is an imbalance of adrenergic outflow.

The EIR model has been used to explain the pathophysiology of PSH, and it takes into account the hypersensitive, overreactive nature of the responses to normal stimuli. Autonomic efferents at the level of the spinal cord are modulated centrally by a balance of sympathetic and parasympathetic inputs from higher brainstem nuclei. Afferents from the spinal cord can modulate this balance in response to stimuli from the environment. The EIR model proposes that the afferent stimuli from the spine have an allodynic tendency, which is normally controlled by tonic inhibitory drive from diencephalic centers. Damage to these inhibitory centers or their inhibitory processes down to the mesencephalon releases the inhibition of the allodynic tendency. Once the tonically inhibitory cycle is broken, there is a positive feedback loop that produces sympathetic overactivity to any afferent stimuli. This model explains how a normally nonnoxious stimulus can become a very noxious stimulus associated with an uncontrolled sympathetic response.

Imaging studies have shown that injury to the deep brain structures, periventricular white matter, corpus callosum, diencephalon, or brainstem may be associated with the development of PSH. PSH is associated with an increased number of lesions in the midbrain and upper pons, compared with number of lesions in cerebral cortex, subcortex, corpus callosum, and diencephalon. Bilateral diencephalic lesions have also been attributed to PSH in hypoxic ischemic encephalopathy. The evidence from imaging studies showing damage to brainstem structures emphasizes the importance of the diencephalic and mesencephalic regions to the pathophysiology of PSH.

DIAGNOSIS

Clinical Manifestations

PSH manifests abruptly in cyclic episodes, either spontaneously or in response to external stimuli. Symptoms are usually first noticed once patients are being weaned off of continuous intravenous sedation and they begin to awaken. The clinical manifestation of PSH define the syndrome: episodic increases in heart rate, blood pressure, respiratory rate, fever, diaphoresis, at times with pupillary dilatation and motor hyperactivity manifested in abnormal posturing, and dystonic movements. Duration of each episodes of exacerbation on average can be minutes to hours and can occur several times a day or in refectory cases nearly continuously. PSH can be difficult to differentiate from opiate withdrawal or agitation from mechanical ventilation. It may persist into the rehabilitation phase and lasts weeks to months after the injury. In severe cases, it may persist for a year.

The overlapping symptoms of PSH with other neurologic sequelae of acute brain injury make the diagnosis difficult and only made after excluding other causes for symptoms. Clinical suspicion and careful examination are of paramount importance in the detection of PSH. Infections, sepsis, pain, opiate withdrawal, and seizures are all diagnoses that have overlapping clinical presentations that need to be excluded in order to diagnose PSH. There are no tests available for confirming the diagnosis of PSH.

Diagnostic Criteria

Recently, a consensus diagnostic criteria has been developed. The paroxysmal sympathetic hyperactivity–assessment measure (PSH-AM) has two assessment tools: the Clinical Feature Scale (CFS) tool and the Diagnostic Likelihood Tool (DLT). The CFS consists of a scoring system from 0 to 3 for the different ranges in the categories of heart rate, respiratory rate, systolic blood pressure, temperature, severity of diaphoresis, and severity of motor posturing. The highest value of the day for each category is counted. The total CFS score can range from 0 to 18, with a score of 0 indicating no PSH-like symptoms and a score of 18 indicating that the patient is exhibiting the most severe PSH-like symptoms for that day (Table 117.1).

Previously, multiple proposed diagnostic criteria overlapped significantly in descriptive ways; consensus regarding specifics of timing, severity, number of episodes did not exist. The DLT aims to address these concerns and exclude other potential diagnoses. This tool involves 11 different criteria focused on timing of symptoms, number of episodes per day, number of consecutive days the patient has PSH-like symptoms, medication administered for sympathetic features, alternate differential diagnoses, and other presumed causes of features. The total DLT score can range from 0 to 11, with a score of 11 representing the highest diagnostic likelihood for PSH (see Table 117.1).

Characteristically, PSH tends to be triggered by minimal external stimuli, such as touching, passive movement (turning, moving limbs, and bathing), or endotracheal tube suctioning. This feature of overreactivity, allodynic response, may be a helpful characteristic for diagnostic purposes. Most of these symptoms have been incorporated into the new diagnostic criteria.

Although PSH can present early after injury, because PSH is a diagnosis of exclusion, the current recommendation is to monitor patients for a minimum of 14 days. The final PSH diagnostic likelihood score is calculated by adding the CFS and DLT score

TABLE 117.1 Paroxysmal Sympathetic Hyperactivity–Assessment Measure[a]

Clinical Feature Scale (CFS)					
	0	1	2	3	Score
Heart rate	<100	100-119	120-139	≥140	
Respiratory rate	<18	18-23	24-29	≥30	
Systolic blood pressure	<140	140-159	160-179	≥180	
Temperature	<37	37-37.9	38-38.9	≥39.0	
Sweating	Nil	Mild	Moderate	Severe	
Posturing during episodes	Nil	Mild	Moderate	Severe	
Severity of clinical features				*Nil*	*0*
				Mild	*1-6*
				Moderate	*7-12*
				Severe	*≥13*

Diagnosis Likelihood Tool (DLT)
❑ Clinical features occur simultaneously.
❑ Episodes are paroxysmal in nature.
❑ Sympathetic over reactivity to normally nonpainful stimuli.
❑ Features persist ≥3 consecutive days.
❑ Features persist ≥2 wk post brain injury.
❑ Features persist despite treatment of alternative differential diagnosis.
❑ Medication administered to decrease sympathetic features.
❑ ≥2 episodes daily
❑ Absence of parasympathetic features during episodes
❑ Absence of other presumed cause of features
❑ Antecedent acquired brain injury
DLT score: 1 point score for each feature present

PSH Diagnosis Likelihood (combined CFS and DLT score)
• *Unlikely <8*
• *Possible 8-16*
• *Probable ≥17*

Abbreviation: PSH, paroxysmal sympathetic hyperactivity.
[a]Adapted from Baguley IJ, Perkes IE, Fernandez-Ortega JF, Rabinstein AA, Dolce G, Hendricks HT; and Consensus Working Group. Paroxysmal sympathetic hyperactivity after acquired brain injury: consensus on conceptual definition, nomenclature, and diagnostic criteria. *J Neurotrauma*. 2014;31(17):1515-1520.

FIGURE 117.1 Combination of medications from different classes likely results in the most effective approach in managing paroxysmal sympathetic hyperactivity. Abbreviations: IV, intravenous; IVP, intravenous push; PSH-AM, paroxysmal sympathetic hyperactivity–assessment measure.

for each day. By calculating the average score for the 14 days during hospitalization, patients can be categorized under "Unlikely" (score <8), "Possible" (score 8-16) or "Probable" (score ≥17) (see Table 117.1).

Patients with high PSH-AM scores are identified as having severe PSH symptoms. However, patients presenting with mild to moderate symptoms are unlikely to be diagnosed with likelihood of PSH in the absence of the PSH-AM. A suggested treatment algorithm is presented on Figure 117.1.

MANAGEMENT

Effective clinical management of PSH requires a combination of pharmacologic as well as nonpharmacologic treatment modalities. Studies examining treatment strategies for PSH are limited, and no level 1 evidence is available to guide the management of PSH. Majority of the studies examining the management of PSH is anecdotal in nature, guided predominantly by case reports and case series. Therapy is focused on control of symptoms. Medical treatments for PSH include opioids, β-blockers, dopamine agonists, α_2-agonists, γ-aminobutyric acid (GABA)ergic agents, benzodiazepines, gabapentin, and muscle relaxants (Table 117.2). The mechanisms by which these agents improve symptoms of PSH remain speculative.

The goal of treatment is to optimize symptom control while minimizing side effects. Treatment should focus on nonpharmacologic management first. Potential stimuli, which can trigger acute episodes of exacerbation should be identified and minimized. Because patients usually are unable to communicate, this process can be difficult but an important first step. Pharmacologic management of PSH focuses on three treatment approaches: maintenance, symptom abortion, and refractory treatment (see Fig. 117.1).

When a paroxysm of hyperactivity occurs, abortive medications are indicated to control discrete breakthrough episodes. These medications have a rapid onset of action with a short half-life. The targets of the abortive medications depend on the predominant symptoms: treating hyperthermia with antipyretics, agitation with sedation, and hypertension with antihypertensive

TABLE 117.2 Medications Used for Treatment of Paroxysmal Sympathetic Hyperactivity

Medication	Location of Action	Proposed Mechanism	Symptoms Treated
Baclofen	Centrally	$GABA_B$ agonist	Pain, clonus, rigidity
Benzodiazepines	Centrally	$GABA_A$ agonist	Agitation, hypertension, tachycardia, posturing
Bromocriptine	Centrally; at hypothalamus	Dopamine agonist	Dystonia, fever, posturing
Clonidine	Centrally; decreased sympathetic outflow	α_2-Receptor agonist	Agitation, hypertension, tachycardia
Dantrolene	Peripherally	Direct-acting skeletal muscle relaxant	Muscle rigidity, posturing
Dexmedetomidine	Centrally; decreased sympathetic outflow	α_2-Receptor agonist	Agitation, hypertension, tachycardia
Gabapentin	Centrally	GABA agonist	Spasticity, allodynic response
Opioids	Centrally; medullary vagal nuclei and peripherally	μ-Opioid receptor agonist	Hypertension, tachycardia, allodynic response
Propofol	Centrally	$GABA_A$ agonist	Agitation, hypertension, tachycardia
Propranolol	Peripherally; decreasing effect of catecholamines	Nonselective β-blocker	Hypertension, tachycardia, fever

Abbreviation: GABA, γ-aminobutyric acid.

agents. Morphine, other opiates, and short-acting benzodiazepines are first-line treatment options for this indication. Dose of medication should be titrated to symptom relief and is limited by the potential side effects, mainly sedation, respiratory depression, and hypotension. Medications with a short half-life should be used for abortive treatment to minimize undesired effects. If frequency bouts of hyperactivity occur, maintenance medication should be adjusted accordingly. Importantly, once the frequency of episodes of exacerbation is controlled, maintenance medications should be aggressively tapered to maximize the alertness of patients.

First-line maintenance pharmacologic agents include medications, which are less sedating and reduce the frequency and intensity of exacerbations. These medications include nonselective β-blockers, α_2-agonists, bromocriptine, baclofen, gabapentin, opiates, and long-acting benzodiazepines such as clonazepam. Propranolol, a competitive nonselective β-blocker, is an ideal drug for controlling symptoms of PSH due to its mechanism of action and broad control of symptoms with minimum sedation. In addition to its cardiovascular effects, propranolol decreases the hyperthermic response to brain injury. Clonidine, a presynaptic α_2-receptor agonist, is a useful agent to manage hypertension and tachycardia. Because increased blood pressure due to excitation of the sympathetic nervous system is one of the major features of PSH, clonidine is often an effective medication. Morphine is a potent μ-opioid receptor agonist. In addition to morphine's analgesic properties, its cholinergic effects and histamine-releasing actions make it a good agent for the management of tachycardia and hypertension. Morphine is the most commonly used medication and can be used as maintenance as well as abortive treatment for breakthrough episodes. Bromocriptine is a synthetic dopamine agonist; the mechanism by which resolution of symptoms including hyperpyrexia and dysautonomia is achieved is unclear. Baclofen, a $GABA_B$ receptor agonist, is indicated for treatment of spasticity associated with PSH and to improve mobility. The benefit is to decrease the number and severity of spasms, thus relieving associated pain, clonus, and muscle rigidity. Benzodiazepines, $GABA_A$ receptor agonists, are useful for symptoms of motor activity, tachycardia, and hypertension. The concern with benzodiazepines is the possibility of worsening neurologic functioning in newly injured brain. A long-acting benzodiazepine, clonazepam, is helpful as a maintenance medication to reduce episodes. Gabapentin, an analog of GABA, was originally developed as an anticonvulsant. However, it may be more useful in the management of painful neuropathies, spasticity, and tremor. It is most useful as an adjunct medication, which is less sedating than benzodiazepines. Dantrolene acts directly on skeletal muscle, decreasing the force of contraction by interfering with release of calcium ion from sacroplasmic reticulum and can be used in cases when severe dystonia or posturing continues to persist. Dantrolene can possibly be effective for the amelioration of dystonic posturing, but the risk of causing hepatotoxicity can limit its use.

Finally, some develop refractory PSH, when symptoms do not respond to isolated intermittent treatment modalities and symptoms become life-threatening. In these cases, continuous intravenous medications with benzodiazepines, opioids, dexmedetomidine, or propofol drips are required. At times, antipyretics with or without temperature control devices is necessitated for aggressive temperature modulation. In addition to continuous infusions of opiates (morphine, fentanyl) and benzodiazepines, dexmedetomidine an α_2-receptor agonist can be administered as a continuous intravenous infusion predominantly for sedation. Given its favorable effects on heart rate, blood pressure, and agitation, dexmedetomidine is a useful intravenous treatment choice. If symptoms are not controlled with other medications, propofol, a general anesthetic, can be used. However, the side effects from the medication limit its use to only severe cases, and it can only be administered with close intensive care monitoring. Unlike dexmedetomidine, patients on propofol require mechanical ventilation support. If posturing persists, the use of intrathecal infusion of baclofen may be helpful. Concerns with using intrathecal infusions include an increase risk in cerebral spinal fluid leak and infection as well as mechanical problems with the catheter or pump. Dopamine antagonists such as chlorpromazine and haloperidol should be avoided because reports of exacerbation of cognitive deficits, psychosis, and neuroleptic malignant syndrome have been reported.

OUTCOME

Although the risk factors and pathobiology remain controversial, the impacts on clinical outcomes are clear. Patients who experience PSH have worse Glasgow outcome scores and worse functional independent measures compared to their counterparts.

Additionally, patients with PSH have longer intensive care unit stays, longer hospital stay, longer mechanical ventilation days, higher infectious episodes, more tracheostomy, and higher health care costs. The mechanisms as to how PSH causes worse outcomes are multifactorial. The symptoms and treatments for the symptoms cause longer period of days on the ventilator, leading to more tracheostomy and longer length of stay. PSH has a direct impact on fever burden after brain injury, which has been associated worse outcomes after brain injury. In addition, the influence of the autonomic nervous system and its effects on inflammation have been studied in other disease states and may be very active in the acutely brain injured population. The dysregulated autonomic nervous system may have an influence in causing unopposed inflammation and leading to secondary brain injury. The availability of a consensus on conceptual definition, nomenclature, and diagnostic criteria is a promising development that will pave the way to a better understanding of the disease.

Sleep Disorders 118

Andrew J. Westwood and Carl W. Bazil

KEY POINTS

1. Sleep is composed of four stages, N1 (5%), N2 (45%), N3 (25%), and rapid eye movement (REM) (25%), and the cycling of these stages comprise the ultradian rhythm.
2. Most REM sleep occurs in the last third of the night.
3. The ventrolateral and median preoptic nuclei are active during sleep and release γ-aminobutyric acid and galanin to inhibit neurons of the ascending arousal system.
4. Individuals with symptoms of insomnia who report daytime sleepiness should be evaluated for other causes than insomnia disorder.
5. Obstructive sleep apnea may mimic many sleep disorders and should be considered in the differential for disorders such as narcolepsy or REM behavior disorder.
6. Sleepiness or snoring are not always present in obstructive sleep apnea.
7. Individuals with narcolepsy present with sleepiness in combination with symptoms such as hypnic hallucinations, sleep paralysis, fragmented nocturnal sleep, and cataplexy. Naps are typically refreshing and vivid dreams may be present in brief naps.
8. Individuals with delayed sleep phase syndrome are often refractory to sedative-hypnotics, report being more awake at night and may fall asleep at a consistent hour later than wanted.
9. Adults experiencing non-REM parasomnias such as somnambulism may have some recall of the events during the night and misdiagnosed as dream enactment behavior.
10. The REM behavior disorder may be a prodrome of neurodegeneration, particularly synucleinopathies such as dementia with Lewy Bodies.

INTRODUCTION

Sleep and sleep disorders are frequently overlooked as a cause or exacerbating factor in neurologic dysfunction. Neuronal activity and the networks involved are different in each state of sleep (non–rapid eye movement [NREM] and rapid eye movement [REM] sleep) compared with the normal waking brain. Sleep and sleep disorders therefore offer unique opportunities to understand the physiology of the brain and its impact on daily functioning. Sleep is involved in the regulation of endocrine and autonomic output and is integral to learning and memory, areas whose complexity and relationship to sleep are only beginning to be understood.

This chapter begins with a brief description of normal sleep and its impact on functioning. An overview of sleep disorders follows with particular relation to their impact on neurologic diseases. Diagnostic testing in sleep is discussed in Chapter 30.

PHYSIOLOGY OF NORMAL SLEEP

Sleep is an active process that involves numerous distinct neuronal networks, which are ultimately expressed as altered physiologic functions. Heart rate, blood pressure, gas exchange, gastrointestinal function, hormonal secretion, and even kidney function are altered during sleep. The exact purpose(s) of sleep remains unclear, but there is considerable evidence of essential associations with immune function, memory, learning, energy conservation, and toxin clearance.

Sleep is classified into stages based on three parameters: electroencephalography (EEG), eye movement or electro-oculography, and muscle tone as assessed by electromyography (EMG) of the mentalis muscle. Arbitrary classification of 30-second recordings, or epochs, divide the process into wakefulness, three stages of NREM sleep (stages N1, N2, and N3), and one stage of REM sleep (stage R).

Wakefulness (stage W) is identified by a low-voltage fast-frequency EEG, high muscle tone, and REMs. *Stage N1* sleep is characterized by a low-voltage, mixed-frequency EEG and slow, rolling eye movements. Reactivity to outside stimuli is decreased, and mentation may proceed but is slowed. *Stage N2* consists of a moderate low-voltage background EEG with sleep spindles (bursts of 12- to 16-Hz activity lasting 0.5-2 s) and K complexes (brief high-voltage discharges with an initial negative deflection followed by a positive component). *Slow-wave sleep (stage N3)* consists of high-amplitude delta (0-2 Hz) frequencies occupying 20% or more of the epoch. During this deeper sleep, heart and respiratory rates are slowed and regular. In NREM sleep, the tonic chin EMG is of moderately high amplitude but less than that of quiet wakefulness (Fig. 118.1).

The EEG pattern during REM sleep (stage R) consists of low-voltage, mixed-frequency activity and is similar to that of stage N1 sleep. Moderately high-amplitude, 3- to 6-Hz triangular waveforms referred to as *sawtooth waves* are intermittently present and are unique to REM sleep. Intermittent bursts of rapid conjugate eye movements occur. Tonic chin EMG activity is absent or markedly reduced, and phasic muscle discharges occur in irregular bursts. The decreased EMG activity is a reflection of muscle paralysis resulting from active inhibition of muscle activity. During REM sleep, surges of parasympathetic and sympathetic activity are denoted by greater variability in heart and respiratory rates. This stage is also associated with complex vivid imagery, but visual imagery can occur in all sleep stages. When occurring in deep NREM sleep, dream images are typically fragmented and may be associated with actions such as the sensation of falling.

FIGURE 118.1 Stages of sleep. Each 30-second recording represents a different stage of sleep. Wake (*W*), non–rapid eye movement is divided into three stages (*N1*, *N2*, *N3*), and rapid eye movement (*R*). For each recording, the top two channels are electro-oculogram (LOC-A2 and ROC-A1); the following six are electroencephalography, followed by chin electromyography and leg electromyography (LAT1-LAT2), airflow, chest and abdominal movements, electrocardiogram, and oxygen saturation.

During a normal night, sleep comprises recurring cycles. Within each cycle of 90 to 120 minutes, NREM sleep alternates with REM sleep. The normal healthy adult typically falls asleep within 10 minutes and goes through the sequence of stages N1 to N3, followed by reversion to stage N2 sleep. Afterward, the first REM sleep period occurs 70 to 100 minutes into sleep. The first REM period is usually the shortest, about 10 minutes. This pattern of NREM and REM sleep is repeated 3 to 5 times during a normal night's sleep. Typically, most stage N3 sleep is seen in the first two sleep cycles, and REM sleep periods increase in duration and intensity of REM activity as the night progresses. Stage N2 sleep, however, is the most common sleep stage, typically making up half of a normal adult's night. In the normal adult, wakefulness accounts for approximately 5% of the night. The N3 and REM sleep typically account for 25% each of total sleep and N1 approximately 5% (Fig. 118.2).

NEUROANATOMY AND NEUROCHEMISTRY OF SLEEP

Evidence from lesions in animals suggest fast neurotransmitters, glutamate and γ-aminobutyric acid (GABA), form the respective core of wakefulness and sleep processes that are modulated by monoaminergic and cholinergic systems. The ascending arousal system has two main pathways: the cholinergic and the group of monoaminergic nuclei. Parabrachial and pedunculopontine glutamatergic neurons feed into the basal forebrain, which in turn sends projections to the reticular nucleus of the thalamus.

FIGURE 118.2 Hypnogram. Graphical representation of sleep stages as a function of time. This hypnogram shows normal sleep architecture with the majority of slow-wave sleep in the first third of the night, rapid eye movement sleep majority in the last third of the night, and progressive longer durations of rapid eye movement.

The monoaminergic pathways pass through the lateral hypothalamus and basal forebrain to reach the cortex by inhibiting the thalamus through GABA transmission this allows thalamocortical transmission to occur.

Wakefulness is inhibited by GABA from the ventrolateral and median preoptic nuclei. As an individual remains awake, sleep pressure builds (resulting from an accumulation of adenosine) until the transition into sleep occurs. There is reciprocal inhibition between the wake and sleep pathways, which allow one state to remain stable and avoiding a shift back and forth between wakefulness and sleep. This has been likened to a "flip-flop" switch where mutual antagonism occurs between the two.

As sleep occurs, brain waves begin to slow and form K waves and sleep spindles. During stage N3 where delta waves predominate, cortical neuronal synchrony is promoted, and this may be related to synaptic pruning. An REM sleep, however, is an activation of cholinergic neurons in the pontine dorsal tegmentum that subsequently excite neurons responsible for REM-associated atonia, rapid eye movements, increase in cortical metabolic rate, loss of thermoregulation, and other features. The REM sleep is inhibited by activation of the dorsal raphe and locus ceruleus. A network of neurons in the hypothalamus midbrain and thalamus seems to regulate REM sleep cycling.

Hypocretin—named so because it structurally resembles secretin in the gut—appears to stabilize the ability to remain awake. It is also referred to as *orexin* codiscovered by another group—named so because of its ability to stimulate food intake (from the Greek *orexis* meaning appetite).

Throughout the 24-hour day, the human body has a symphony of endocrinologic and metabolic variations that are timed to maximize performance during wakefulness and promote quality rejuvenation during sleep. Because we evolved on a planet that rotates every 24 hours, we developed a delicate neurochemistry anticipatory cycle that prepares the body for the upcoming sleep-wake state. This circadian cycle is approximately 1 day as captured in the Greek meaning of *circadian*. Many body functions, including body temperature, plasma and urine hormones, renal functions, psychological performance measures, and internal sleep-stage organization, participate in this circadian rhythm. Humans have a circadian rhythm that is approximately 24.3 hours and is driven by an intrinsic pacemaker in the suprachiasmatic nucleus. This nucleus is influenced by external time clues to synchronize the body clock with the outside world, including bright light, activity, meals, and social interactions. Evidence for the importance of circadian rhythms comes from studies of acute phase shifts, such as those that occur after jet lag or shift work. Because our internal clock is longer than 24 hours, adaptation is slower after an eastward flight (phase advance) than after a westward flight (phase delay).

SPECIFIC DISORDERS OF SLEEP

Nearly all patients with disorders of the central nervous system (CNS) are at high risk for sleep dysfunction, which may be a direct result or a secondary effect of the neurologic condition. Sleep disorders may exacerbate the symptoms of the underlying neurologic disorder and impair quality of life. In this chapter, we describe selected disorders. *Fatal familial insomnia*, a prion disease, is discussed in Chapter 55. Sleep-associated headache disorders and epilepsy syndromes are also discussed in their respective chapters.

Insomnia

Insomnia *symptoms* can consist of difficulty falling asleep (sleep-onset insomnia), difficulty staying asleep (sleep maintenance insomnia), both, early morning awakenings, or sleep that is nonrefreshing or nonrestorative. The daytime symptoms include excessive fatigue (physical tiredness), impaired performance, or emotional change. Most people have an occasional night fraught with difficulty falling asleep or trouble maintaining sleep, usually caused by an alerting response to short-term stress; this is a normal property of the brain and is not considered insomnia if it resolves quickly.

Confusion often arises from using the term *insomnia* to describe symptoms as well as a medical disorder. Insomnia *disorder* is a diagnosis of exclusion and is a subjective disorder requiring no objective evidence to support it. Generally, those with insomnia disorder do not report daytime sleepiness (although may report fatigue); in those with sleepiness, other sleep disorders should be considered.

Diagnosis

In the past, insomnia disorder has been categorized into primary or secondary types, but these were difficult to reliably ascertain. Insomnia disorder is now considered as *short-term*, *chronic*, or *other* LEVEL 2.[1]

Short-term insomnia lasting less than 3 months duration might be closely linked to the surrounding events, psychological disturbances, or sudden changes in a medical condition. Typically, there is an identifiable precipitant that an individual is able to recall. Individuals may complain of disturbances fewer than 3 times per week, but this results in a general dissatisfaction in their quality of sleep. It may also result in the individual catastrophizing that they may never sleep again. The 1-year prevalence of short-term insomnia is around 20% in the general adult population. Circadian rhythm disorders should be considered as mimickers of insomnia. In delayed sleep phase syndrome, individuals typically complain that they cannot fall asleep until later in the night and due to morning commitments have to curtail their sleep, and this results in sleep deprivation. Early morning awakening raises the possibility of advanced sleep phase if the patient falls asleep early in the evening. Alcohol also characteristically causes this symptom.

Chronic insomnia, lasting greater than 3 months on 3 or more days per week, is usually attributed to multiple factors. The factors may be divided into predisposing, precipitating, and perpetuating, which outline the formation of insomnia as an ongoing process. Characteristics that predispose an individual for insomnia are female gender, older age, psychiatric or chronic medical illness, lower socioeconomic status, poor education, obsessive-compulsive nature, poor coping strategies, and hyperalertness (Table 118.1). In general, those with insomnia disorder are not sleepy individuals—they report an inability to sleep under any circumstance.

Insomnia may be precipitated by sudden changes in environment or challenges to the body or mind. These challenges may come in the form of acute medical illness, psychological or psychiatric events, shift in schedule, or changes in medications or supplements. After the start of the insomnia, patients adopt behaviors or rituals that perpetuate the insomnia. Patients may use maladaptive habits that occur during the day or night and include heavy caffeine or alcohol use; watching television, working, or playing video games while in bed; or even eating or exercising during the usual sleep period. They may

TABLE 118.1 Principles of Good Sleep Hygiene Are the Basis for a Sound Night of Sleep

Principles of Sleep Hygiene
• Establish regular bedtimes.
• Wake regularly at a fixed time.
• Regulate the amount of sleep obtained each night.
• Exercise daily and regularly (particularly aerobic) but not in the late evening.
• Sleep in a quiet, cool, comfortable environment.
• Avoid caffeinated beverages and other stimulants (including tobacco) especially close to bedtime.
• Avoid alcohol within 3 h of bedtime.
• Avoid hypnotic drugs.
• Do something relaxing before bedtime.
• Use the bedroom only for sleep and sexual activity.

become dependent on certain somnogenic substances. Some patients develop associations of not sleeping with the bedroom and may fear going to bed. These poor associations and expectations of poor sleep promote the apprehension toward sleep. The insomnia symptom complex may indicate an underlying disorder related to primary failure of the sleep mechanism or one in which sleep disruption is a result of another disorder. Patients with obstructive sleep apnea, restless legs syndrome, and even narcolepsy may complain of insomnia. Sleep diaries, accounting bedtime and wake time, can be useful in determining potential links to schedule or circadian rhythm issues. Perception of good sleep is an important factor in evaluating the complaint of insomnia.

Some patients may embellish their symptoms, whereas other patients may not perceive they are asleep. These individuals display the normal physiologic parameters of sleep but do not recognize that they have slept. This is referred to as *sleep-state misperception* or *paradoxical insomnia*.

Insomnia symptoms may also be produced by medical or neurologic disorders. Derangement of almost any system in the body can disrupt sleep. Patients with diseases affecting the nervous system, heart, liver, kidneys, gastrointestinal tract, or lungs commonly complain of insomnia symptoms. Musculoskeletal discomfort such as in arthritis or other rheumatologic disorders may become worse with periods of rest. Pain from entrapment neuropathies such as carpal tunnel are typically worse at night, and headaches such as cluster headache or pain related to increased intracranial pressure or brain mass lesions can become more intense during sleep. Nearly all of the psychiatric illnesses have some link to poor sleep. Patients with depression or anxiety disorders may have insomnia years prior to the presentation of the affective component. Insomnia symptoms may also herald the onset of psychosis or mania. Insomnia symptoms can be triggered by many medications and sometimes adjusting the time of administration can benefit the individual.

Management

Treatment of insomnia disorder should be directed toward symptom improvement and avoidance of maladaptive behaviors. Therapy for neurologic and psychiatric disorders should be optimized, and a multipronged approach addressing the patient's behaviors, psychological attitudes, and the potential underlying neurochemistry should be constructed. Cognitive behavioral therapy for insomnia consisting of sleep restriction therapy, relaxation therapy, stimulus control, and sleep hygiene (see Table 118.1) provides a solid therapeutic foundation. Cognitive behavioral therapy for insomnia is the most effective long-term therapy for insomnia and where available should be offered first line for chronic insomnia disorder. This is becoming more readily available in self-help book formats as well as online subscription sites. The use of acupuncture for insomnia remains equivocal due to the lack of methodologic consistency in the trials LEVEL 1.[2]

There are also a number of safe, effective hypnotic substances that may be used particularly in short-term insomnia disorder to help restore normal sleep patterns and reverse negative associations with sleep time and the bedroom environment. These differ mainly in half-life, with zaleplon (5-20 mg) very short acting, zolpidem (5-10 mg) short, and eszopiclone (1-3 mg) the longest (therefore most useful in sleep maintenance insomnias). Ramelteon (8 mg) is a melatonin agonist that is also a mild hypnotic. Suvorexant (5-20 mg) is the first nonselective dual orexin antagonist and, more recently, lemborexant (5-10 mg) received U.S. Food and Drug Administration (FDA) approval. When these agents fail, benzodiazepines and sedating antidepressant drugs are alternatives. Short-acting benzodiazepines are usually preferable to avoid daytime sedation, although if anxiety is also present, longer acting compounds can be useful. Many medications are used off-label for insomnia particularly if there are concomitant symptoms that could be effectively treated at the same time, such as headaches or depression. Many medications typically used for insomnia have not received formal approval by the FDA because they have not applied for insomnia as a specific indication. Substances that promote alertness should be minimized when possible, and additional medicinal therapy should be directed toward a specific disease process. The goal of treatment with any hypnotic should be to help restore normal sleeping patterns, followed by a planned slow elimination of the drug (Table 118.2).

When an individual has less sleep than what is generally considered normal, concern may arise from those around them. Some individuals are *short sleepers* requiring less than 6 hours of sleep but do not complain of sleep/wake disturbances and therefore are not insomniacs per se—they do not have daytime impairment. Others may spend excessive amounts of time in bed. This pattern may occur, for example, from parents allocating too much time for their children to sleep, but the child functions normally. Some adult individuals are *long sleepers*, requiring 10 or more hours of sleep to function without signs of sleep deprivation. Although frustrating to patients, this condition is best treated with longer sleep times so long as no other source of ineffective sleep is found.

The Hypersomnias

Sleepiness is defined as the propensity to enter sleep. Fatigue in contrast is related to physical and/or mental exhaustion but does not result in sleep. Sleepiness is a normal feeling as one approaches a typical sleep period, but excessive sleepiness occurs when one enters sleep at an inappropriate time or setting. Excessive sleepiness can occur in degrees. In mild sleepiness, one might have only limited impairment, such as falling asleep while

TABLE 118.2 A List of Current Medications Approved by the FDA for Insomnia[a]

	FDA-Approved Pharmaceutical Treatment of Insomnia			
Class	**Agent**	**Dosage (mg)**	**Half-life (h)**	**Comments**
Nonbenzodiazepine–benzodiazepine receptor agonists	Zaleplon	5-20	1	—
	Zolpidem	5 (women) 5-10 (men)	1.4-3.6	Available as oral, oral spray, and sublingual forms
	Zolpidem ER	6.25-12.5	1.4-3.6	Women metabolize zolpidem at a lower rate than men.
	Eszopiclone	1-3	5-7	—
Orexin antagonist	Suvorexant	5-20	8-14	Do not use in patients with narcolepsy.
	Lemborexant	5-10	17-19	
Benzodiazepines	Estazolam	0.5-2	10-24	—
	Flurazepam	15-30	47-100	—
	Quazepam	7.5-15	47-100	—
	Temazepam	7.5-30	8-20	—
	Triazolam	0.0625-0.125	1.5-5.5	—
Tricyclic antidepressants	Doxepin	3-6	8-24	Approved in low-dose 3- and 6-mg formulations only
Selective melatonin receptor agonist	Ramelteon	8	8	—

Abbreviation: FDA, U.S. Food and Drug Administration.
[a]Many others are used off-label.

reading a book. Greater degrees of sleepiness, however, may be associated with bouts of irresistible sleep or sleep attacks that intrude on such activities as driving, having a conversation, or eating meals. This degree of sleepiness places the patient at significant risk for accidents and has a major impact on the person's well-being. It must occur for at least 3 months prior to diagnosis.

Clinicians should always question their patients with hypersomnia for clues of potential sleep debt, sleep disorders, or other medical or psychiatric causes. Sleep deprivation is the most common cause of sleepiness. Information regarding sleep habits, schedule during the week and weekends, and environment often discloses other important contributing factors. Excessive sleepiness may result from a wide range of medical disorders and medications. Patients with heart, kidney, or liver failure or rheumatologic or endocrinologic disorders such as hypothyroidism and diabetes may note sleepiness and fatigue. Neurologic disorders such as strokes, tumors, demyelinating diseases, epilepsy, and head trauma can evoke excessive sleepiness. Sleepiness is frequently the cardinal symptom of many sleep disorders (Table 118.3). Patients with sleep apnea, narcolepsy, restless legs syndrome–periodic limb movements, or even parasomnias may note excessive daytime sleepiness as their main complaint. Thus, the clinician should question the patient further to elucidate potential etiologies.

About 2% of men and 1.5% of women report sleeping at least 10 hours per night and are regarded as *long sleepers* (in children, it is 2 h more than the age-specific normative data). The additional sleep time is spent in REM and N2 compared to other individuals. Providing that these individuals obtain sufficient sleep prior to testing, the multiple sleep latency test (MSLT) is normal.

Narcolepsy

Narcolepsy is an incurable lifelong neurologic disorder characterized by the tetrad of (1) excessive daytime sleepiness, (2) cataplexy, (3) sleep paralysis, and (4) hypnagogic hallucinations. Patients with narcolepsy also typically have fragmentation of nocturnal sleep.

Epidemiology

Estimates of prevalence range between 2 and 10 per 10,000 individuals in North America and Europe. It is about 5 times more prevalent in Japan, and the incidence is only 1 per 500,000 in Israel. The symptoms of narcolepsy typically present between ages 10 and 30 years, although cases have been reported with onset as early as age 2 years and as late as 76 years. Men and women are equally affected. There appears to be a bimodal distribution occurring in teenage years and later around age 35 years.

TABLE 118.3 Differential Diagnosis of Excessive Daytime Sleepiness

- Insufficient sleep syndrome
- Sleep apnea syndromes
- Narcolepsy
- Idiopathic hypersomnia
- Demyelinating disease
- Infections
- Sarcoidosis
- Neurodegenerative diseases
- Tumors of the hypothalamus or rostral midbrain
- Metabolic disorders, for example, hypothyroidism, pancreatic insufficiency, renal insufficiency, hepatic encephalopathy
- Drugs, for example, antidepressants, hypnotics, and antihistamines
- Withdrawal of stimulants
- Periodic limb movement disorder
- Circadian rhythm disorders
- Depression

Clinical Features

Symptoms gradually develop over several years, but once it has fully developed, there is usually only a minor fluctuation in the severity. Sleepiness is often minimized or thought to be related to other causes, and diagnosis can be delayed for years or even decades. As weight gain and depression are common, other causes for excessive daytime sleepiness in a previously well-rested individual should be considered.

Diagnosis

Type 1 narcolepsy requires an abnormal MSLT (as described in Chapter 30) and/or cerebrospinal fluid (CSF) hypocretin-1 concentration, measured by immunoreactivity to be less than 110 pg/mL. Cataplexy does not need to be present if hypocretin-1 levels are below 110 pg/mL. Ten percent of individuals with cataplexy will not have hypocretin-1 levels below this cutoff and are now considered to be narcolepsy type 2. Narcolepsy type 2 is diagnosed if the patient has an abnormal MSLT but cataplexy is absent or CSF measurements are greater than 110 pg/mL (or not measured). In the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, narcolepsy with the absence of cataplexy is considered *primary hypersomnia*.

Narcolepsy has been associated with several of the human leukocyte antigen (HLA) subtypes. *DQB1*0602* is found in isolation in African Americans and together with *DR2/DRB1*1501* in Caucasians and Asians. Most with narcolepsy type 1 will have the *DQB1*0602*, but it is also found in 12% to 38% of the general population. The risk of narcolepsy type 1 in first-degree relatives is approximately 1% to 2%.

Identification of the hypocretin-orexin gene and receptors in mouse models and humans revealed that narcolepsy type 1 is associated with loss of hypocretin-orexin–producing neurons in the lateral hypothalamus. Hypocretin-orexin in the CSF is found low in patients with cataplexy. Brains from narcolepsy patients show a loss of hypocretin-orexin–producing neurons. This loss of hypocretin-orexin–producing neurons is thought to permit the rapid switching between sleep and wake states.

Narcolepsy

Narcolepsy is a disorder of sleep-wake stability. Patients have bouts of irresistible sleep during wakefulness and frequent arousals during sleep. Intrusion of fragments of REM sleep into wakefulness is most evident in the presence of the symptoms of cataplexy, sleep paralysis, and hypnagogic hallucinations.

Daytime sleepiness is usually the first and most prominent symptom to appear, but hyperactivity may be seen in children as they attempt to fight off sleep. Patients often complain of attacks of irresistible sleep that occur at inappropriate times, such as during conversation, driving, and eating. Brief naps for some are refreshing. The symptom of excessive daytime sleepiness is disabling and often leads to personal, social, and economic problems.

Cataplexy

Cataplexy is the abrupt onset of paralysis or weakness of voluntary muscles without change in consciousness; it is typically precipitated by strong emotions. Events can be triggered by a joke, surprise, anger, fear, or athletic endeavors. These events last seconds to minutes, and patients have clear memory for the complete event with no postictal confusion or deficits. Longer events may proceed to the patient entering sleep. The severity of cataplexy is variable. Some patients may have as few as two or three episodes in a lifetime, whereas others may have several episodes every day. A full range of severity exists between these extremes. Cataplexy may be partial and affect only certain muscles; common examples include dysarthria; drooping of the head, face, and eyelids; and slight buckling of the knees. Severe global attacks affect all skeletal muscles except muscles of respiration and cause collapse. Onset of the attack usually takes seconds with brief moments of partial regaining of muscle tone at the beginning. Examination of the patient during the cataplectic attack will demonstrate paralysis with diffuse hypotonia, absence of deep tendon reflexes, diminished corneal reflexes, preserved pupillary responses, and phasic muscle twitching with preserved consciousness. Reflexes can be preserved in partial cataplexy. Phasic muscle twitching can occur as single jerks or repetitive muscle twitching and is most frequently seen in the face. Most episodes last only seconds to 1 minute, but severe attacks can last minutes. Sudden withdrawal of antidepressants can result in status cataplecticus. Cataplexy typically follows onset of excessive daytime somnolence, usually beginning within 5 years if present.

The combination of excessive daytime sleepiness and cataplexy is nearly always related to narcolepsy. Cataplexy can rarely be seen as an isolated symptom, suggesting an underlying neurologic disorder. Cataplexy has been reported in cases of demyelinating disease, stroke, and Niemann-Pick type C. The historical feature of clear emotional triggers differentiates cataplexy from hypotension, vertebral basilar insufficiency, and the group of neuromuscular disorders known to produce periodic paralysis. Autoimmune or paraneoplastic disorders associated with the aquaporin-4 or anti-Ma2 as well as myotonic dystrophy, parkinsonism, and severe head trauma can also present with narcolepsy.

Sleep Paralysis

Sleep paralysis is a global paralysis of voluntary muscles that occurs at the entry into or emergence from sleep. These events may include the feeling of being chased or impending danger. The terror associated with the events can be recounted by the patient years later. The events are aborted with a tactile stimulation. The paralysis associated with the event is thought to result from the same motor inhibition that occurs in REM sleep. Sleep paralysis without narcolepsy can occur in an isolated form in sleep-deprived healthy individuals but is also frequently seen in patients with depression. Prevalence of a single episode of sleep paralysis is estimated to be between 15% and 40% of the general population. Differential diagnoses for sleep paralysis should include cataplexy, atonic seizures, and familial periodic paralysis syndromes.

Hypnic Hallucinations

Hypnic hallucinations are vivid dreamlike images that occur during sleep onset (hypnogogic) or at sleep offset (hypnopompic). They may include simple to complex visual, auditory, or somatosensory hallucinations. Patients are usually aware of their surroundings and may have difficulty in discerning the hallucinations from reality. The hallucinations can be relatively pleasant or terrifying. Patients may note a feeling of weightlessness, falling, or flying or have out-of-body–like experiences that may sometimes terminate with a sudden jerk (hypnic jerk). Hypnic hallucinations are most likely the result of dissociated CNS processes involved in dreaming during REM sleep. They can be

TABLE 118.4 Comparison Between the *ICSD-3* and the *DSM-5* for the Criteria of Narcolepsy Variants

	Narcolepsy-Hypocretin Deficiency (DSM-5)	Primary Hypersomnia (DSM-5)	
	Narcolepsy Type 1 (ICSD-3)	Narcolepsy Type 2 (ICSD-3)	Idiopathic Hypersomnia (ICSD-3)
Findings on MSLT	<8 min with two or more SOREMPs	<8 min with two or more SOREMPs	<8 min and fewer than two SOREMPs[a]
Cataplexy	Present	Rarely present	Absent

Description of naps	Short and refreshing	Short and refreshing	Long and unrefreshing
Sleep efficiency	Low	Low	High (>90%)

Abbreviations: CSF, cerebrospinal fluid; *DSM-5, Diagnostic and Statistical Manual of Mental Disorders*, 5th edition; *ICSD-3, International Classification of Sleep Disorders*, 3rd edition; MSLT, multiple sleep latency test; SOREMPs, sleep-onset rapid eye movement periods.
[a]If longer than 8 min, the individual must have 11 h of sleep in a 24-h polysomnogram or averaged from 7-d wrist actigraphy.

precipitated by sleep deprivation, medications, and alcohol in normal individuals. Hallucinations typically accompany sleep paralysis in 25% to 75% of cases.

Management

The current treatment for the sleepiness of narcolepsy is the use of stimulant/wake-promoting drugs, behavioral modifications, and/or γ-hydroxybutyrate (6-9 g). The stimulants can be categorized into the amphetamine and nonamphetamines types. Modafinil (100-200 mg), armodafinil (the R-enantiomer of modafinil [150-250 mg]), and solriamfetol (75-150 mg) are wake-promoting agents chemically and pharmacologically distinct from the amphetamine stimulants LEVEL 4.[3] Pitolisant (17.8-35.6 mg) is an H3-inverse agonist and antagonist. Use of stimulant drugs should be carefully monitored; patients and physicians should cooperate in adjusting the amount and timing of doses to meet functional daytime needs and scheduling of patients' activities. Cataplexy, when present to a significant degree, is usually well controlled with the selective serotonin reuptake inhibitors (paroxetine hydrochloride [20-60 mg] or fluoxetine hydrochloride [20-60 mg]) and tricyclic compounds (imipramine hydrochloride [10-100 mg], protriptyline hydrochloride [5-60 mg], or clomipramine [10-150 mg]); however, impotence and reduced libido may occur. These medications are thought to treat cataplexy effectively because they suppress REM sleep. γ-Hydroxybutyrate (6-9 g) is given at bedtime and again during the night to improve sleep and reduce the frequency and severity of both sleepiness and cataplexy. Due to its potential for abuse, it is highly regulated and only available from a single central pharmacy. Pitolisant has evidence of anticataplectic effect in addition to its wake-promoting properties, although currently does not have FDA approval for this indication.

An important adjunctive treatment for narcolepsy is the rational scheduling of daytime naps, two 20-minute naps, for example, and the maintenance of proper sleep hygiene. The physician's role in providing the patient with a clear understanding of the nature of the symptoms and with emotional support in coping with the many adaptive difficulties cannot be overemphasized.

Outcome

Narcolepsy symptoms produce major social, familial, educational, and economic consequences for both the patient and the family. Patients often do not achieve their intellectual potential and suffer frequent failures of occupation, education, and marriage. Family members, friends, and even patients often interpret the symptoms as indicating laziness, lack of ambition, delayed maturation, or psychological defects. Because these symptoms begin during the crucial period of maturation from puberty to adulthood, misinterpretation and lack of diagnosis can greatly affect a patient's personality and feelings of self-esteem (Table 118.4).

Kleine-Levin Syndrome

Kleine-Levin syndrome (recurrent hypersomnia) consists of recurrent episodes of hypersomnia and binge eating lasting from 2 days to 5 weeks (rarely to 80 d), with intervals less than 18 months between episodes. Neurobehavioral and psychological changes, such as disorientation, automatic behavior, forgetfulness, depression, depersonalization, hallucinations, irritability, aggression, and sexual hyperactivity, often accompany the episodes of hypersomnia. During the episodes, the EEG shows general slowing with 0.5- to 2-second bursts of bisynchronous generalized moderate- to high-voltage 5- to 7-Hz waves. This resolves in between episodes. Onset is typically in early adolescent in boys and is less common in girls. Prevalence is estimated to be around one or two cases per million. Episodes decrease in frequency and severity with age and are rarely present after the fourth decade. Differential diagnosis for this condition includes encephalitis, hyperammonemic encephalopathy, demyelinating disease, head trauma, porphyria, basilar migraine, and complex partial status epilepticus as well as psychiatric conditions such as depression, seasonal affective disorder, or somatoform disorder. A menstrual variant of this condition has been reported in 18 women worldwide.

A definitive treatment for Kleine-Levin syndrome is not known, but there are reports of limited success with stimulants (especially amantadine [100-200 mg]), sodium valproate (250-60 mg/kg), carbamazepine (up to 1,200 mg/d) and antidepressant therapy (including lithium [300-1,800 mg]).

Sleep-Related Breathing Disorders

Control of respiration during sleep is an excellent model of state-dependent neuronal regulation. Respiratory patterns vary with sleep stage. Near sleep onset, occasionally, individuals will have normal pauses in breathing. Mild periodicity to breathing can be noted in light sleep, but on entrance into slow-wave sleep, breathing is very regular and response to high carbon dioxide and low oxygen levels is blunted. During REM sleep, chest musculature is paralyzed and ventilation occurs only via diaphragmatic movement. The REM sleep is also characterized by significant variation in respiratory pattern and the least response to high carbon dioxide levels and low oxygen. Each of these stages allows for the expression of dysfunction in the regulation of breathing during sleep. Some individuals with brain or

cardiac pathology may express dramatic periodic breathing or Cheyne-Stokes respiration in NREM sleep, whereas others who have impairment of ventilation owing to diaphragmatic impairment or impediment will demonstrate hypoventilation during REM sleep. More commonly, individuals may have obstruction of the upper airway during sleep.

Snoring

Snoring is created by turbulent airflow vibrating upper airway soft tissue and is more prominent during inspiration and loudest during N3 and REM sleep (the periods of greatest muscle relaxation). Snoring occurs in approximately two-thirds of adults, more commonly in men, and in over 10% of children. Persistent loud snoring is a classic symptom of obstructive sleep apnea syndrome (OSAS), but the absence of snoring does not exclude the diagnosis. Some patients' airways do not resonate to produce snoring. This is especially true in patients who have had upper airway surgical procedures that tightened tissue. Other individuals may not generate enough inspiratory force, such as those with neuromuscular disorders.

Sleep Apnea

Apnea refers to a pause in breathing, and on overnight sleep studies, the pause must persist for at least 10 seconds to be considered apnea. *Hypopneas* are defined as the partial reduction in airflow for a similar time. These respiratory events are accompanied by oxygen desaturation and/or arousals. Apneas and hypopneas are typically more prevalent during light NREM sleep and REM sleep.

Clinical Features

Historically, bed partners may describe these events as though the breathing has stopped or the patient is holding his or her breath during sleep. These events may be aborted with a loud gasp, snort, body jerks, or the quiet resumption of breathing. Some patients have hundreds of events per night and are unable to obtain quality sleep. These individuals are typically unaware of any sleep disruption but feel unrefreshed in the morning. Patients with neurologic disorders are also at higher risk for sleep apnea. Sleep apnea is more commonly seen in individuals with CNS disease such as epilepsy, strokes, and head trauma and "classical" peripheral disease such as muscular dystrophy and myotonic dystrophy. Sleep apnea is classified into two major forms: obstructive and central.

Obstructuve Apnea

Obstructive apnea is the most common form of sleep apnea. These apneas occur due to obstruction or collapse of the upper airway. The OSAS is the cluster of features including snoring, witnessed apneas, excessive daytime sleepiness, insomnia, morning headache, and impairment of daytime performance caused by the repetitive apneas. However, up to half of patients with documented obstructive sleep apnea on overnight polysomnography have no complaints of daytime symptoms. The OSAS is frequently seen in individuals with hypertension, diabetes mellitus, and vascular disease. In adults, OSAS occurs predominantly between the fourth and sixth decades and is more common in men. The prevalence of OSAS increases with age and is higher in individuals with habitual snoring and obesity. The protective effects of estrogen is lost after menopause, and the incidence in men and women becomes similar. Many patients are obese, yet some have normal body habitus. Common structural abnormalities such as narrow nasal passage, long soft palate, large tonsils, or retrognathia leading to a small airway contribute to airway obstruction. Individuals with CNS disease are found to have a higher prevalence of sleep apnea than the general population.

The OSAS is an independent risk for hypertension and the development of vascular disease. Recognized systemic complications of OSAS are systemic hypertension, pulmonary hypertension, diabetes mellitus, cardiac enlargement, myocardial infarction, stroke, elevated hematocrit, and an increased risk of sudden death during sleep.

Sleep apnea also occurs in infants and children. In infants, sleep apnea is associated with familial, congenital, and acquired dysautonomia syndromes and craniofacial disorders. Distinguishing apnea from normal periodic breathing is critical in infants, as some of these disorders are associated with either central or obstructive apneas. In children, obstructive sleep apnea is often associated with adenotonsillar hypertrophy, and daytime sequelae of hyperactivity, poor school performance, behavior problems, and limited growth have been associated.

Central Apnea

Central apnea is the absence of ventilation owing to an absence of generation of respiratory effort. Central apneas can cause complaints of frequent awakenings and restless unrefreshing sleep. These respiratory events can be caused by neurologic abnormalities involving respiratory regulatory neuronal networks. Apneas may also follow neurologic events such as nocturnal seizures or acute strokes. One form of periodic breathing, Cheyne-Stokes breathing, can be seen in individuals with heart/renal failure, neurologic lesions, and metabolic or toxic encephalopathies. Patients with central apnea need a complete cardiac and neurologic examination. Certain medications such as opiates or use of alcohol may also result in central sleep apnea.

Mixed Apnea

When a single event is a combination of the two, the term *mixed apnea* is used. The term *complex sleep apnea* has no standard definition and should be avoided. Some may use it to describe an individual who has both central and obstructive events on diagnostic testing; others use it to describe the emergence of central events when obstructive events are treated.

Management

Treatment for sleep apnea consists primarily of methods of promoting airway patency for obstructive apnea and stimulation of breathing in central apnea.

CPAP

Continuous positive airway pressure (CPAP) is the most common and effective treatment. Constant air pressure is generated by a small pump and delivered via tubing to a mask covering the nose and/or mouth. Patients may be given this treatment during polysomnography to determine the pressure required to alleviate airway obstruction during sleep. Autotitrating devices alter the pressure depending on the level of resistance; these can be prescribed for most individuals without in-laboratory titrations. In some circumstances, the positive airway pressure may need to be altered in both inspiration and expiration to maximize each breath—bilevel CPAP. In some cases of central sleep apnea, adaptive servoventilation may be required. These devices provide variable support to overcome the oscillations between hyperpneas and hypoventilation seen in this condition and

may reduce mortality in certain individuals. However, there is some evidence of increased in mortality in using this ventilatory mechanism in those with heart failure. It is unclear whether treatment is needed for individuals where central sleep apnea is related to opioid use. This breathing pattern resolves with cessation of the offending medications LEVEL 1.[4]

In those with neuromuscular disorders, volume-assured pressure support may be indicated although there is no clear benefit compared to bilevel CPAP. It can, however, adapt as the disease progresses. Typically, those with progressive neuromuscular disorders are monitored with nocturnal oximetry for evidence of sleep-related hypoventilation.

In individuals unable to tolerate any devices but have desaturations during sleep, oxygen may be prescribed. However, there is limited evidence whether sleep-related desaturations (with the absence of wake-related desaturations) are deleterious to health.

Key elements for compliance with positive airway pressure therapy include patient education of the importance of therapy, close follow-up, and addressing patient problems with the therapy. Oral appliances advancing the mandible are reasonable alternative therapies for patient with mild sleep apnea particularly if unable to tolerate positive airway pressure.

Other Treatments

The level of obstruction in obstructive sleep apnea may be found at various levels of the airway. In some patients, especially children and young adults, the removal of enlarged tonsils and adenoids relieves the obstruction. Stimulation devices of the airway have recently been developed to reduce the risk of airway collapse during sleep. The surgical procedure, uvulopalatopharyngoplasty, has been an inconsistently beneficial treatment, and selection criteria are not well established. Genioglossal and maxillary-mandibular advancements have successfully treated patients with structural abnormalities causing hypopharyngeal obstruction. Other treatments for less severe cases have been sustained weight loss and (for those with significant sleep apnea only when supine) sleeping in the lateral position. Neurostimulatory devices targeting the hypoglossal nerve can be effective in those unable to tolerate or to adequately respond to other therapies.

Hypoventilatory and Hypoxemic Disorders

Several causes of hypoventilation during sleep are known and require detection of hypercarbia (sleep-related hypoxemia requires a diagnosis of hypoxia). *Obesity hypoventilation syndrome* results in sleep as well as wake hypercarbia and requires a body mass index of 30 or to be greater than the 95th percentile for age and sex in children. *Congenital central alveolar hypoventilation syndrome*, previously called *Ondine's curse*, is a syndrome of the automatic central control of breathing due to the *PHOX2B* gene. It must be distinguished from mimickers such as Chiari malformation, obesity hypoventilation syndrome, Leigh disease, or congenital heart disease when cor pulmonale coexists. *Late-onset central hypoventilation with hypothalamic dysfunction* presents after the first few years of life with hyperphagia and respiratory failure from minor provocation. Temperature dysregulation, precocious puberty, thyroid disease, and other endocrinologic disorders may occur from inappropriately elevated or reduced levels of hypothalamic hormones.

Catathrenia

Catathrenia is the term associated with sleep-related groaning typically associated with a prolonged expiration that disturbs the bed partner or family members. It is more common in men although remains rare. There are no known long-term consequences of it and it can be treated effectively with positive airway pressure.

SLEEP-RELATED MOVEMENT DISORDERS

Restless Legs Syndrome and Periodic Limb Movement Disorder

Periodic limb movements in sleep (PLMS) are found in most patients with restless legs syndrome who are studied with polysomnography but are more commonly associated without symptoms of restless legs syndrome. Although most patients do not complain of symptoms related to the PLMS, patients or their bed partner may notice leg or arm movements during sleep. These movements may occur as periodic events or appear random. The PLMS are repetitive stereotyped movements of any of the extremities. These most commonly occur in NREM sleep and activate the lower extremities as extension of the great toe with dorsiflexion of the ankle and flexion of the knee and hip. Movements can also occur in the arms and axial muscles. The individual movements are relatively brief, lasting 0.5 to 5.0 seconds, occur at 20- to 90-second intervals, and may continue for minutes to hours. Limb movements may be accompanied by an arousal or awakening. In contrast to most movement disorders, which are diminished by sleep (eg, cerebellar and extrapyramidal tremors, chorea, dystonia, hemiballism), PLMS are initiated by sleep or drowsiness. They are also different from *hypnic jerks* (sleep starts), which are normal, nonperiodic, isolated myoclonic movements. Similar to restless legs syndrome, periodic limb movements are provoked by uremia, anemia, peripheral neuropathy, antiemetics, antidepressants, and caffeine use.

In individuals with restless legs syndrome, limb movements can be seen on the polysomnography. Periodic limb movements of sleep, however, are not necessary and are not correlative with restless legs syndrome. Eighty percent of sufferers have periodic limb movements of sleep. Periodic limb movements during wakefulness have also been noted and have been proposed as a better marker.

Restless legs syndrome is discussed in detail in Chapter 78. It is important to note that restless legs syndrome is a clinical diagnosis based on questioning the individual. It does not require a sleep study to diagnose.

In a case of hypersomnia where all medical causes, psychiatric diseases, and other sleep disorders have been excluded and the only abnormality is periodic limb movements, then *periodic limb movement disorder* is diagnosed. Periodic limb movement disorder is mutually exclusive of restless legs syndrome. There is limited literature on the treatment but is empirically treated with similar therapeutic approaches as restless legs syndrome.

Sleep-Onset Movements

Some movements occur at the transition between wake and sleep. *Sleep-related rhythmic movement disorder* involves large muscle groups moving in a stereotyped repetitive fashion that is not a tremor. It may involve the head, torso, or limbs in isolation. Sleep-related movement disorder is common in children and typically does not require treatment except protection from

injury if movements are violent. It rarely persists into adulthood, in which case it can be disruptive to bed partners and treated with low-dose clonazepam (0.25-1 mg). When smaller muscle groups are involved, other diagnoses such as bruxism, thumb sucking, or hypnagogic foot tremor, excessive fragmentary myoclonus should be considered. *Propriospinal myoclonus* results in difficulty initiating sleep and affects mainly the abdomen, trunk, and neck. When it is persistent into the daytime, a structural cause is found in 15% to 20% of cases. It typically spreads slow to rostral and caudal muscles from the axial muscles. *Sleep starts* or *hypnic jerks* involve one or more body segments in a single contraction and often asymmetrically. These may occur in association with a sensory component such as loud noise or a sensation of falling. Sleep deprivation, excessive stimulants, prior intense exercise, and emotional stress can increase frequency and severity of sleep starts. They are also prominent in heredity hyperekplexia LEVEL 1.[5]

Sleep-Related Movements

Body movements may occur during sleep such as the presentation of parasomnias or sleep-related leg cramps. *Benign sleep myoclonus of infancy* occurs only in sleep, whereas myoclonic seizures and myoclonic encephalopathy will also occur in wakefulness.

Circadian Rhythm Disorders

Disorders of the circadian sleep-wake cycle are divided into two major categories, transient and persistent. The *transient disorders* include the temporary sleep disturbance following an acute work shift change and a rapid time zone change (jet lag). Both sleep deprivation and the circadian phase shift produce symptoms including insomnia symptoms and excessive sleepiness. These disorders usually resolve as external and internal cycles become aligned. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, removed jet lag disorder from its list of conditions; however, the *International Classification of Sleep Disorders* still recognizes its existence.

Other disorders are more persistent. Sleep-wake cycle disorders that persist are divided into several major clinical categories. Persons who voluntarily and frequently change their sleep-wake schedule (eg, shift workers) have a mixed pattern of excessive sleepiness alternating with arousal at inappropriate times of the day or have minimal circadian pattern. Sleep is typically short and disrupted. Waking is associated with a decrease in performance and vigilance. This syndrome often disrupts social and family life.

Delayed Sleep Phase

The *delayed sleep phase type* is a specific chronobiologic sleep disorder characterized by going to bed late and waking up late in the morning. Patients are typically unable to fall asleep earlier and go to sleep between 1 and 6 AM. On weekends and vacation days, they sleep until late morning or early afternoon and feel refreshed but have great difficulty awakening at the required 7 or 8 AM for work or school. These patients have a normal sleep length and internal organization of sleep when clock time of sleep onset and sleep offset coincides with the circadian timing that controls daily sleep.

Successful treatment has been a phase shift of the time of the daily sleep episode by progressive phase delay of the sleep time. By delaying the time of going to sleep and awakening by 2 or 3 hours each day (ie, a 26- or 27-h sleep-wake cycle), the patient's sleep timing can be successfully reset to the preferred clock time. Additionally, treatment with bright light in the morning and melatonin (0.2-0.5 mg) or a melatonin agonist in the evening may help shift and lock the circadian rhythm to a desired schedule LEVEL 1.[6]

Advanced Sleep Phase

The *advanced sleep phase type* is a condition in which individuals go to bed early in the evening and wake early in the morning. Typical sleep onset is between 6 and 8 PM, with wake times between 1 and 3 AM despite efforts to delay sleep time. This pattern is more likely to occur in elderly persons. Treatment of bright light in the evening and extended-release melatonin may help the sleep-wake schedule.

Nonentrained and Irregular Sleep Phase

The rare individual with the free running type or *nonentrained type* maintains a 25- to 27-hour biologic day that does not entrain to the world's 24-hour cycle. This is more common in individuals who have prechiasmatic blindness, as light stimulus (a primary zeitgeber) does not reach the suprachiasmatic nucleus. This is in contrast to a person with an *irregular sleep-wake type* consisting of considerable irregularity without an identifiable persistent sleep-wake rhythm. There are frequent daytime naps at irregular times and a disturbed nocturnal sleep pattern. This disorder indicates dysfunction of the pacemaker, and most patients with this syndrome have congenital, developmental, or degenerative brain dysfunction, although it does occur rarely in cognitively intact patients. Treatment is difficult but should include regularly scheduled activities and time in bed based on sleep hygiene principles.

Nocturnal Behaviors

Parasomnias

Parasomnias are undesirable physical or behavioral phenomena that occur predominantly during sleep. They include disorders of arousals, such as sleepwalking or night terrors; sleep-wake transition disorders, such as sleep talking; and REM parasomnias, such as REM sleep behavior disorder (RBD). These behavioral events may mimic epileptic seizures or other psychiatric events. Key features of age of onset, time of night of the events, stereotypic behavior, memory for the events, and family history are important in historically distinguishing the etiologies. Although RBD is the only disorder requiring polysomnography for diagnosis, most patients require polysomnographic recording (with complete EEG if epilepsy is in the differential) to delineate the cause or other potential sleep disorders provoking the parasomnia.

Non–Rapid Eye Movement Parasomnias

The classic disorders of arousal occur out of slow-wave sleep and include *sleepwalking, sleep terrors*, and *confusional arousals*. These behaviors are more common in children and adolescents and are characterized as events occurring as partial arousals from the deeper stages of NREM sleep. These patients are caught in a transition of part of the brain in NREM sleep and another portion in wake. These nonstereotypic events are more common in the first half of the night (when N3 is more prevalent), and typically, patients have little to no memory for the events; recall may increase with age. Sleepwalking usually involves a series of simple motor behaviors, such as sitting up in bed, walking, opening and closing doors, or climbing stairs, however, can rarely result in jumping out of bed as well as violent behaviors.

Other automatic behaviors such as eating (sometimes of inappropriate substances) or sexual behavior can occur. Higher cognitive functions are significantly impaired, and there is reduced vigilance although motor behavior is intact. Self-injury and injury to those around them can occur.

Sleep terrors, however, start with a piercing scream or fright with significant sympathetic nervous system output. Patients have tachycardia, pupillary dilation, and sweating and appear wide eyed and inconsolable. A subgroup of patients may be harmful to themselves or others, such as fighting, throwing objects, and climbing out or walking through a window.

Confusional arousals occur following sudden awakening and may be accompanied with disorientation and the patient striking out. Other variations include sleep-related eating disorder, which is hallmarked by patients eating in a messy, haphazard manner with little or no recall. Sleep-related abnormal sexual behaviors can involve masturbatory behavior and sexual vocalizations and may have criminal consequences due to the initiation of sexual intercourse, molestation, or assault.

A small nightly dose of a benzodiazepine, such as clonazepam (0.25-4 mg) or temazepam (7.5-30 mg), is useful, especially when potential exists for the patient or bed partner to be injured. Medication such as zolpidem, phenothiazines, anticholinergics, and lithium may provoke these episodes. Hypnosis has also been used. Generally, treatment is not required, but safety is a priority especially when the individual has a tendency to leave the bed.

Rapid Eye Movement Parasomnias

RBD, a REM sleep–related parasomnia, is characterized by intermittent loss of REM sleep atonia with dream enactment. Patients usually have clear recall of the dream, and witnesses can relate the activity to the dream mentation. Events are more likely to occur in the latter half of the night (when REM is more prevalent) and do not have stereotypic behavior. Injury to self or bed partner is common. Up to 80% of middle-aged adults may develop signs of a synucleinopathy (such as Parkinson disease, dementia with Lewy bodies, or multiple system atrophy) within a decade of their RBD onset. Some studies also suggest that if individuals are monitored over several decades 100% will develop evidence of a syncleinopathy. This association is less clear when idiopathic RBD begins at a younger age. The prevalence of RBD is unknown but appears to be more common in older men. Some patients may develop RBD due to structural lesions interrupting the REM atonia pathway. Medications such as serotonin reuptake blockers and norepinephrine reuptake blockers have been cited to result in RBD-like behavior, although there is no evidence currently that these predispose to the condition.

The diagnosis is usually suggested by history and is required to be confirmed by polysomnography. Recordings show persistent muscle tone and complex behaviors during REM sleep. Most patients respond to clonazepam (0.25-4 mg) at bedtime, but success has been reported with melatonin (2-12 mg) and donepezil (10-15 mg) LEVEL 3.[7] Modifications to the sleeping environment are sometimes required to avoid self-injury and to those around them, such as bedrails, sleeping on a mattress on the floor, or placing the individual in a sleeping bag (Table 118.5).

Other REM parasomnias include painful erections, nightmares, and REM sleep–related sinus arrest, which are beyond the scope of this chapter.

Anti-IgLON5 (a neuronal cell adhesion protein) disease first described in 2014 is a heterogeneous disorder presenting with REM behavior disorder, NREM parasomnias, sleep-related breathing as well as gait abnormalities, cognitive dysfunction, and bulbar symptoms. This disease typically occurs after the age of 60 years. It is unknown if it is a primary tauopathy with a secondary immune response or a primary autoimmune disease. HLA-DRB1*10:01 and HLA-DQB1*05:01 are associated with the disorder.

TABLE 118.5 Differential Diagnosis of Dream Enactment Behavior

• REM behavior disorder
• Severe obstructive sleep apnea
• Periodic limb movement disorder
• Frontal lobe epilepsy
• Disorders of arousal
• Oneiric stupor
• Hallucinations in dementia
• Confusional awakenings in dementia
• Dissociative disorder

Abbreviation: REM, rapid eye movement.

CONCLUSION

Nearly every CNS process has been associated with disruption of sleep. The ubiquity of sleep and the brain makes this dynamic relationship even more important. Sleep may be abnormal because of involvement of brain structures that control and regulate sleep and wakefulness or because of abnormal movements or behaviors that occur during sleep. Additionally, the loss of sleep provokes further dysfunction of the brain. For example, patients with epilepsy have fewer seizures once treated for their previously unrecognized obstructive sleep apnea. Other small studies have shown patients with neuromuscular disorders improve their daytime function when their sleep-related respiratory disturbances are treated. As neurologists, we must be keenly aware that sleep provides another dimension of diagnostic and therapeutic avenues for diseases of the nervous system. More importantly, perhaps, we need to be vigilant for sleep disorders contributing to morbidity in our patients, particularly as nearly all are treatable, potentially resulting in increased quality of life.

Heart-Brain Interactions 119

Shouri Lahiri and Stephan A. Mayer

KEY POINTS

1. Acute stroke after cardiac procedures can occur due to arrhythmia, hypoperfusion, thromboembolism, and coagulopathy.
2. Risks and benefits of antithrombotic medications should be considered in patients with acute stroke due to cardiac devices.
3. Reversibility is a hallmark feature of neurogenic stunned myocardium.
4. β-Blockers are a first-line treatment for paroxysmal sympathetic hyperactivity.

INTRODUCTION

The heart-brain interaction is a vital physiologic circuit often implicated in neurologic and cardiovascular injury. Cerebral complications of cardiac procedures and stroke due to atrial arrhythmias represent important causes of neurologic disability. Recent advances and complications of cardiopulmonary support with left ventricular assist device (LVAD) and extracorporeal membrane oxygenation (ECMO) have opened the door to new neurologic diagnostic and therapeutic challenges. Conversely, severe acute brain injury is being increasingly recognized as a cause of catecholamine-mediated myocardial dysfunction, an entity that is known by many names (Table 119.1) but is most accurately described as *neurogenic stunned myocardium* (NSM).

Autonomic storming is similarly caused by exaggerated sympathetic effect after brain injury and is characterized by cardiovascular abnormalities including coexistent hypertension and tachycardia. Neurogenic hypotension in the absence of cardiac dysfunction usually results from abnormal vasomotor tone and is discussed in Chapter 116.

CEREBRAL COMPLICATIONS OF CARDIAC PROCEDURES

Epidemiology

Cerebrovascular injury is one of the most feared complications of cardiac surgery. Ischemic strokes occur in 0.8% to 5.2% of coronary artery bypass graft (CABG) surgeries, although the incidence may be decreasing with more recent publications from 2011 reporting incidence closer to 1.6%. One single-center study of more than 45,000 patients found that 40% of the strokes occurred intraoperatively with the postoperative risk for stroke peaking at 40 hours following surgery. The risk for stroke is greater for patients undergoing CABG with aortic atherosclerosis and concomitant carotid artery disease, and the risk is directly proportional to the degree of stenosis. Other risk factors for perioperative stroke with CABG include atrial fibrillation, prior stroke or transient ischemic attack, and female gender. Cognitive disability in the absence of acute infarct occurs in up to 70% of patients following CABG. The reported incidences of postoperative cognitive decline are widely variable and likely reflect variability of the cardiac procedure itself to differing neuropsychiatric testing methods and control groups.

Atrial fibrillation occurs in up to 40% of patients within a few days following CABG. It occurs in up to 50% of patients after valve surgery and up to 60% of patients following valve replacement plus CABG. Eleven percent of patients develop atrial fibrillation as a late complication of CABG. In the general population, the most common causes of atrial fibrillation are hypertension, coronary heart disease, and rheumatic heart disease, with the latter being uncommon in developed countries. The risk of ischemic stroke due to atrial fibrillation may be stratified using scoring systems such as $CHADS_2$, which incorporate additional risk factors for stroke including heart failure, advanced age, diabetes, prior stroke, female gender, etc. Refer to Chapter 45 for a detailed discussion of stroke risk due to atrial fibrillation.

LVAD and ECMO have dramatically changed the therapeutic landscape of severe, medically refractory cardiopulmonary failure. Neurologic complications are, however, common and occur in 8% to 25% of patients with LVADs. In a series from the University of Pittsburgh Medical Center, 61% of LVAD-related neurologic complications were due to embolic strokes, and 25% were intracerebral hemorrhages. In another single-center study from Columbia University, 14% of patients with LVADs developed neurologic complications of which 81% were either due to ischemic or hemorrhagic stroke. A recent review on LVAD-related bleeding and thrombosis from 2012 found that the incidence of ischemic strokes was 0.04 to 0.13 per patient-year

and 0.05 to 0.8 per patient-year and for hemorrhagic strokes. Relatively, little has been reported on the neurologic complications of adult patients on ECMO. In one series, 50% of patients receiving ECMO suffered neurologic injury of which 17% were strokes defined as either ischemic stroke, hemorrhagic stroke, or subarachnoid hemorrhage. The frequency of neurologic events was likely underestimated in this study because less than one-third of the patients underwent cerebral imaging.

Pathobiology

The majority of strokes after cardiac surgery are ischemic, although hemorrhagic conversion of ischemic infarcts is possible. Intraoperative strokes occur due to arterial emboli arising from atherosclerosis of major vessels such as the aorta or carotid arteries or due to cerebral hypoperfusion resulting from intraoperative hypotension or diminished cardiac output. Fat and air emboli may also occur. Transcranial Doppler ultrasonography monitoring of the middle cerebral artery has been used to quantify microemboli during coronary bypass surgery, which in some cases exceed 60 per operation. High-risk periods for embolization include manipulation of the heart and aorta, particularly during aortic clamping and cannulation. No causal relationship has been confirmed between number of microemboli and cognitive decline, although increased burden of new ischemic lesions has been associated with postoperative cognitive decline. Other factors that are thought to contribute to cognitive impairment after CABG include relative cerebral hypoperfusion, anesthesia, and systemic inflammatory effects.

Postoperative strokes are generally cardioembolic and related to postoperative arrhythmias such as atrial or ventricular fibrillation. Cerebral complications of atrial fibrillation occur due to embolization of thrombus from the left atrium or atrial appendage. Strokes due to atrial fibrillation are more likely to cause large-vessel occlusion and hemispheric injury than embolic sources arising from the carotid arteries. This was demonstrated in a study that showed that cardioembolic etiologies of stroke were 25 times likely to cause hemispheric events than retinal events. The presumed mechanism for this difference is the larger size of cardioembolic particles compared to emboli arising from the carotid arteries.

LVADs pose extraordinary challenges related to coagulopathy. Although anticoagulation is required to decrease risk of device thrombosis and thromboembolism, this comes at the cost of increased hemorrhagic complications. Furthermore, high-shear stress conditions related to LVADs are thought to induce an acquired von Willebrand syndrome by mechanical destruction of von Willebrand multimers. As a result, LVAD patients are at higher risk for both hemorrhagic and ischemic strokes. Hemorrhagic strokes in patients with mechanical circulatory devices should raise suspicion for endocarditis. The role of infections and inflammatory milieu on neurologic complications is an ongoing debate in patients both with and without mechanical circulatory devices. In one study of LVAD patients, 42% of cerebrovascular accidents occurred in patients with infections. An elevated white blood cell count was noted in patients with neurologic complications regardless of the presence or absence of infection, although it is unclear whether this represented a stress reaction from acute brain injury. The same study found thromboelastogram abnormalities in periods with infection than without infection suggesting that infection may activate platelet function and contribute to the risk of neurologic injury.

Similar to the LVAD, anticoagulation is required to decrease the risk of ECMO-related thrombosis and thromboembolism. Also analogous to the LVAD, increased platelet activation and consumption due to exposure to foreign surface area is common, further contributing to a bleeding diathesis. The net result is a significantly increased risk of bleeding in up to 40% of patients receiving ECMO. Thromboembolic complications are more common in venoarterial compared to venovenous ECMO because blood is infused directly to the systemic circulation with the former. Greater risk of retrograde aortic blood flow and stasis of the blood due to worsening left ventricular output also increase the risk of thrombus formation.

Diagnosis

Initial diagnosis of stroke is suggested by history and physical examination and then corroborated by neuroimaging. The clinical manifestation of stroke reflects the dysfunction of the affected neuroanatomic structures. Although hemiparesis is a common symptom of stroke, it is not an invariable finding because isolated aphasia syndromes may also be encountered. When hemiparesis is present, it may be limited to hand or fine finger movements and mistaken for a compression neuropathy. Approximately 20% of ischemic strokes involve the posterior circulation and can present with subtle eye movement abnormalities, behavioral changes, and cortical blindness—a constellation of symptoms that raise suspicion for the potentially devastating "top of the basilar" syndrome. Although there is overlap between the clinical presentations of ischemic and hemorrhagic strokes, the latter is more likely to have a more fulminant presentation with prominent impairment consciousness and rapid progression of symptoms. Neuroimaging remains an essential tool to distinguish between ischemic and hemorrhagic stroke etiologies.

The National Institute of Health Stroke Scale is a reliable 15-item scale that is validated as a measure of stroke impairment (see Chapter 16). Computed tomography of the brain is often used as an initial diagnostic test for intracranial hemorrhage because hyperacute ischemic changes may not be evident. Magnetic resonance imaging of the brain with diffusion-weighted imaging may detect ischemic abnormalities as early as within 3 minutes of symptom onset; however, it may be contraindicated in patients with metallic devices such as LVADs and certain pacemakers. Blood cultures, fungal cultures, and transesophageal echocardiograms should be obtained when there is a suspicion for endocarditis and septic emboli and particularly in patients with mechanical circulatory devices. Cerebral angiography may be indicated to diagnose mycotic aneurysms.

Management

Prevention

It is critical to employ measures to prevent neurologic complications during cardiac surgery. Preoperative evaluation involves assessment of risk factors including carotid stenosis. The risk of stroke during cardiac surgery may be lowered by performing simultaneous carotid endarterectomy. Avoiding relative hypotension during cardiac surgery may improve outcomes. This was shown in a randomized trial of 248 patients where maintaining higher pressures (mean artery pressures 80-100 vs 50-60 mm Hg) during cardiopulmonary bypass was significantly associated with lower rates of neurologic and cardiac complications or death at 6 months LEVEL 1.[1] More recent studies suggest a potential role for targeting individualized blood pressure goals based on cerebral autoregulation indices. Systemic hypothermia at 32°C for closed chamber and 28°C for open chamber procedures during cardiopulmonary bypass may reduce

cerebral metabolic rate and prevent ischemia. Transesophageal echocardiogram reduces the risk of intraoperative strokes by enhanced detection of aortic atheroma enabling the surgeon to alter technique to reduce risk of embolization. Electroencephalography can also be used to detect cerebral ischemia during cardiac surgery, although the use of this is debated.

Acute Ischemic Stroke

Thrombolytic therapy is often contraindicated for acute ischemic stroke during the postoperative period and in patients being treated with therapeutic levels of anticoagulation. Strokes occurring due to septic emboli from infected hardware also increase the risk of hemorrhage due to thrombolysis. Alternative reperfusion techniques including endovascular therapies may be considered in the appropriate circumstances. In patients with LVADs or patients receiving ECMO, the benefits of anticoagulation for thromboembolism need to be balanced with the risks of hemorrhagic conversion of ischemic infarct for a given patient based on stroke severity, size, and timeline. There are currently limited data on the optimal time frame for restarting antithrombotics; however, significant delays in restarting these medications further increase the considerable risk of thromboembolism. Other management strategies of acute ischemic stroke are discussed in Chapter 16.

Intracranial Hemorrhage

Intracranial hemorrhage is primarily a risk of LVAD and ECMO support due to the need for anticoagulation, acquired Von Willebrand factor deficiency, and concurrent risk of brain embolism. Initial management should involve discontinuation of all antiplatelet medications and anticoagulation. Anticoagulation reversal should be strongly considered for life-threatening hemorrhages with the understanding that these interventions may increase the risk of device thrombosis in patients with cardiopulmonary devices. Hemostatic therapy should be tailored to the specific anticoagulant exposure (see Table 39.3). For example, protamine sulfate may be used for heparin-related intracerebral hemorrhage, and vitamin K with prothrombin complex concentrate/fresh frozen plasma may be used for warfarin-related intracerebral hemorrhage. Targeted antidotes for factor Xa inhibitors (inactivated coagulation factor Xa), direct thrombin inhibitors, antifibrinolytics, and recombinant factor VIIa may also be considered in the appropriate clinical setting. Platelet transfusions or desmopressin (DDAVP) may be considered for selected patients. Blood pressure should be managed as per current guidelines (see Table 40.2). Endocarditis should be treated with antibiotics and surgical evaluation (see also Chapter 65). There is currently limited data on when to restart antithrombotics after intracerebral hemorrhage. A rational approach that balances the risk of hemorrhage expansion with the considerable benefits of thromboembolic prophylaxis based on the individual clinical circumstance is appropriate until further research is available.

Outcome

Perioperative stroke increases hospital mortality by up to 10-fold, and long-term survival is worse among stroke survivors. A study by Tarakji et al found that perioperative stroke decreased the likelihood of survival at 1, 10, and 20 years by 25%, 41%, and 23%, respectively.

In the Randomized Evaluation of Mechanical Assistance for the Treatment of Chronic Heart Failure trial, cerebrovascular complications were the third leading cause of death (9.8%). This finding was supported by two other publications; 1 of over 1,000 LVADs where a central nervous system event was the third leading cause of mortality accounting for 14% of deaths. Little has been reported on neurologic complications of adult ECMO patients. This may be in part due to the difficulty in knowing whether the neurologic consequences are the result of the pathology prompting ECMO or related to the ECMO process itself. In one series, 63% of subjects who underwent cerebral imaging had pathologically abnormal findings, and 90% of patients who underwent brain autopsy had evidence of intracranial pathology ranging from ischemic/hemorrhagic lesions to diffuse cerebral edema. In one study of infants receiving ECMO, major intracranial hemorrhage accounted for 55% of deaths.

CARDIOVASCULAR COMPLICATIONS OF NEUROLOGIC INJURY

Neurogenic Stunned Myocardium

Epidemiology

NSM may be defined as an acute, reversible cardiac injury commonly associated with various forms of acute brain injury including subarachnoid hemorrhage, intracerebral hemorrhage, ischemic stroke, and seizures. Electrocardiographic abnormalities are seen in up to 70% of patients with subarachnoid hemorrhage and in up to 40% of patients with intracerebral hemorrhage and ischemic stroke. Left ventricular systolic dysfunction has been found in 10% to 28% of patients with subarachnoid hemorrhage, and diastolic dysfunction is seen in up to 71% of patients.

Pathobiology

NSM is presumed to occur due to dysregulation of autonomic control, primarily of the sympathetic system. A proposed instigating mechanism is injury to the insular cortex or hypothalamus, which are important areas for autonomic control. Right cerebral hemispheric injury is more likely to be associated with sympathetic dysautonomia, whereas the left cerebral hemisphere predominantly causes parasympathetic responses. Similar neuroanatomic specialization was demonstrated in cats where lateral hypothalamic stimulation caused sympathetic responses such as tachycardia and ST-segment depressions, whereas anterior hypothalamic stimulation caused parasympathetic responses such as bradycardia. There is evidence that primary brainstem injury in the setting of transtentorial herniation can also produce a massive sympathetic discharge. All of these states are characterized by abnormal hyperactivity of the locus coeruleus, a nucleus in the pons that mediates sympathetic tone.

Catecholamine release and overload, primarily released by the cardiac sympathetic nerves, produces a state of overstimulation of myocardial cells with a characteristic histopathology termed *contraction band necrosis*. Affected myocardial cells are overloaded with calcium, remain hypercontracted, and no longer respond to β_1-receptor agonists due to uncoupling of the adenyl cyclase secondary messenger system. For this reason, attempts to improve left ventricular contractility with exogenous catecholamines such as norepinephrine in patients with cardiogenic shock tend to be ineffective.

Clinical Features

NSM tends to occur in the setting of acute severe brain injury. Subarachnoid hemorrhage is the best known and most common cause of NSM, but the condition can develop in response to any

cause of massive sympathetic outflow, including intracerebral hemorrhage, cerebral infarction with herniation; Guillain-Barré syndrome; acute hydrocephalus; traumatic brain injury; or status epilepticus, acute emotional stress, and pheochromocytoma. Mild to moderate elevations in cardiac enzymes may accompany characteristic electrocardiographic features, which include long QT intervals, widespread symmetric inverted T waves, and U waves. Left ventricular dysfunction manifests as diastolic dysfunction in mild cases. More severely affected patients develop regional left ventricular wall motion abnormalities that do not respect typical vascular territories in association with mild to moderate reduction of the left ventricular ejection fraction (20%-40%). In fulminant cases, patient can develop acute cardiogenic shock with ejection fractions of 20% or less. The level of cardiac enzyme elevation is typically low in relation to the extent of left ventricular dysfunction. A retrospective study to differentiate between acute coronary syndrome and NSM found troponin levels were 10-fold higher with infarcted heart (based on historic controls) compared to stunned myocardium (2.8 vs 0.22 ng/mL). A troponin level of less than 2.8 ng/mL and ejection fraction less than 40% in the setting of acute aneurysmal were consistent with stunned myocardium rather than acute coronary syndrome.

Acute neurogenic pulmonary edema (NPE) can occur in isolation, or in addition to, NSM. In its purest sense, NPE is thought to represent a neurally mediated noncardiogenic form of pulmonary edema characterized by disruption of the integrity of the pulmonary microvasculature (ie, "leaky lung" pulmonary edema). Acute peripheral vasoconstriction has been shown to cause a massive increase in intrathoracic blood volume, which causes a "blast effect," which then leads to increased pulmonary vascular permeability (Fig. 119.1).

Diagnosis

The takotsubo variant of NSM features characteristic echocardiographic findings of apical akinesis and ballooning with left ventricular diastolic and systolic dysfunction (▶ Video 119.1). It is important to appreciate that NSM occurs on a spectrum of variants that includes a "reverse takotsubo" pattern where the apex of the heart is normal and the base is hypokinetic (▶ Video 119.2). If clinical suspicion is high for acute coronary syndrome, coronary angiography may be required to definitively exclude underlying coronary artery disease. Serial echocardiography by definition shows progressive improvement and eventual normalization of left ventricular function over days to weeks.

Treatment and Outcome

Patients with severe acute intracranial pathology should have continuous electrocardiographic monitoring for at least 72 hours, and cardiac enzymes should be obtained. Management should be focused on treating the underlying cause of the neurogenic stunning such as securing the ruptured aneurysm. Euvolemia should be maintained using isotonic intravenous (IV) fluids as needed. There is evidence from cohort studies that NSM is less common among subarachnoid hemorrhage patients previously on β-blockers; for this reason, there may be some rationale for use of the β_1-blocker esmolol (starting at 50 μg/kg/min, titrated to attain heart rate below 100 beats/min). When cardiac function is significantly diminished, inotropic vasopressors or inotropes such as norepinephrine, dobutamine, and milrinone may be required to augment cardiac output. There is evidence that milrinone, a phosphodiesterase inhibitor, is a more effective inotrope than norepinephrine because it bypasses β_1 receptors, which are prone to receptor desensitization. NPE tends to be fragile and often responds to gentle diuresis with furosemide. Reversibility is a hallmark feature of NSM, and echocardiographic abnormalities usually improve within days.

Paroxysmal Sympathetic Storming

Synonyms for paroxysmal sympathetic storming include autonomic storming, paroxysmal dysautonomia, autonomic dysfunction syndrome, hypothalamic-midbrain dysregulation syndrome,

FIGURE 119.1 Diagram explaining how neurogenic stunned myocardium and pulmonary edema characterized by increased pulmonary vascular permeability can coexist after subarachnoid hemorrhage (SAH) and other forms of catastrophic brain injury. The unifying inciting event is a massive catecholamine discharge **(b)**, which leads to concomitant decreased left ventricular contractility and leaky lung pulmonary edema after the initial phase of injury **(c)**. Abbreviations: LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Adapted from Mayer SA, Swarup R. Neurogenic cardiac injury after subarachnoid hemorrhage. *Curr Opin Anaesthesiol*. 1996;9:356-361.)

paroxysmal autonomic instability with dystonia, and neurostorming. The condition is characterized by irregular, recurrent violent sympathetic discharges in the acute or subacute phase of severe brain injury in the intensive care unit.

Epidemiology

Paroxysmal sympathetic storming occurs in up to 33% of patients with severe traumatic brain injury and severe diffuse axonal shearing injury and is also relatively common in patients with anoxic brain injury. It is less frequently seen in patients with poor-grade subarachnoid hemorrhage, coma resulting from intracerebral hemorrhage, malignant middle cerebral artery infarction syndrome, and brainstem pathology. It seems to be more common in younger patients.

Clinical Features

Autonomic storming presents with paroxysmal episodes of hypertension and tachycardia, fever, hyperventilation, diaphoresis, extensor posturing, and severe dystonia. The onset typically occurs days to weeks after the original brain injury event. The posturing and dystonia may at times resemble generalized seizures consistent with prior descriptions of autonomic storming as "diencephalic seizures."

Diagnosis

Autonomic storming is a clinical diagnosis. A diagnostic algorithm is summarized in Table 119.2. One of the easiest ways to make the diagnosis is to establish the presence of episodic parallel urges in blood pressure and heart rate when reviewing vital signs over 24 hours on a bedside monitor. Seizures may need to be excluded using continuous video electroencephalography because the episodes are often paroxysmal. Autonomic storming may need to be differentiated from the typical pressor response to elevated intracranial pressure or cerebral ischemia, which is a common compensatory sequel of acute brain injury and likely reflects efforts to maintain adequate cerebral perfusion pressure in the face of elevated intracranial pressure.

TABLE 119.2 Diagnostic Criteria for Paroxysmal Sympathetic Storming

Four of the following, occurring in episodic surges at intervals of 30 min-4 h:
• Fever (>38.3°C)
• Tachycardia (120 beats/min or 100 beats/min if on β-blockers)
• Tachypnea (respiratory rate >30 breaths/min)[a]
• Hypertension (systolic blood pressure >160 mm Hg or pulse pressure >80 mm Hg)
• Diaphoresis
• Extensor posturing or motor dystonia
• Severe dystonia

[a]In the absence of sepsis or airway obstruction.

Management

Management of sympathetic storming is focused on brain sedation, analgesics that blunt nociceptive inputs that trigger storms, agents that specifically suppress the locus coeruleus, and blunting of the peripheral manifestations of hypertension and tachycardia with β-blockers. Acute control of severe symptoms can be quickly attained with infusion of propofol (50-200 μg/kg/min), fentanyl (50-100 mg/h), or dexmedetomidine (0.7-1.4 μg/kg/h) alone or in combination (Fig. 119.2).

Pharmacotherapeutic options to control symptoms and allow weaning of analgosedative infusions in the intensive care unit

FIGURE 119.2 Suppression and stabilization of sympathetic storming with propofol infusion in a patient with paroxysmal sympathetic storming. Note the immediate stabilizing effect on intracranial pressure (ICP), which fell from levels as high as 70 mm Hg to normal at the start of the infusion. Abbreviations: HR, heart rate; MAP, mean arterial pressure.

TABLE 119.3 Pharmacotherapy for Paroxysmal Sympathetic Storming During the Subacute to Chronic Phase

Analgosedatives	• Fentanyl patch 25-300 μg/h • Morphine (Roxanol, MS Contin) 5-20 mg every 4 h • Lorazepam 2-24 mg/d • Klonopin 1-8 mg/d
β-Blockers	• Propranolol 160-640 mg/d • Labetalol 400-3,600 mg/d
Central antiadrenergic agonists	• Clonidine patch 0.1-0.9 mg/d • Bromocriptine 10-40 mg/d
Muscle relaxants	• Baclofen 10 mg 3 times a day • Dantrolene orally 25-100 mg 4 times a day
Anticonvulsants	• Gabapentin 900-3,600 mg/d

are summarized in Table 119.3. These agents should be started sequentially and evaluated during daily interruptions of continuous IV analgosedation. Concurrent use of IV antihypertensive agents such as nicardipine or labetalol is rarely needed after IV sedative agents have been administered. It is important to realize that neurogenic autohypertension is fragile and can be easily overtreated and result in impaired cerebral perfusion pressure. As such, antihypertensive medications may need to be started at lower doses and titrated up while monitoring response.

Outcome

Paroxysmal sympathetic storming typically persists for weeks to months before it resolves. Storming treated with prolonged IV infusions of analgosedatives such as propofol and fentanyl leads to increased intensive care unit length of stay and a concomitant increase in the risk of hospital-acquired infections and complications. Outcome can be improved by aggressively advancing the agents used for subacute to chronic control of symptoms in Table 119.3, which allows discontinuation of IV sedation, liberation from the ventilator, and advancement to rehabilitation.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

Sepsis-Associated Encephalopathy 120

Aurélien Mazeraud, Cássia Righy, Stephan A. Mayer, and Tarek Sharshar

KEY POINTS

1. Sepsis-associated encephalopathy (SAE) is a key manifestation of sepsis, occurring in up to 70% of patients admitted to the ICU.
2. SAE is associated with increased hospital mortality and worse long-term cognitive and functional outcomes.
3. The pathophysiology of SAE involves neurotransmitter dysfunction, inflammatory and ischemic lesions to the brain, microglial activation, brain-barrier dysfunction, and stress network activation.
4. Delirium, a common manifestation of SAE, is mostly diagnosed with validated scales in the ICU population.
5. Non-pharmacological prevention of delirium is key for managing SAE, including avoiding over-sedation (particularly with benzodiazepines), early mobilization, and sleep promotion.

INTRODUCTION

Since ancient times, physicians have recognized that the central nervous system is one of the first organs affected in sepsis. Sepsis, defined as a life-threatening organ dysfunction caused by a dysregulated host response to infection, is a leading cause of intensive care unit (ICU) admission and death worldwide. The incidence of encephalopathy in the setting of sepsis is about 50% but can vary from 8% to more than 70%. Sepsis-associated encephalopathy (SAE) is often the revealing manifestation of sepsis and alteration in mental status has been identified as one of three critical screening items for identifying high mortality risk in the patients with suspected infection (Table 120.1).

TABLE 120.1 The Quick Sequential Organ Failure Assessment Score[a]

Risk Factor	Points
Altered mental status (GCS <15)	1
Respiratory rate ≥22/min	1
Systolic blood pressure ≤100 mm Hg	1
Risk Level	**Total Points**
Low risk (<5%) for mortality	0-1
High risk (5%-20%) for mortality	2-3

Abbreviation: GCS, Glasgow Coma Scale.
[a]See also qSOFA.org.

FIGURE 120.1 Early signs observed during sepsis **(left column)**, relying on specific structures **(middle column)** and associated to worst outcome **(right column)**. Whereas sickness behavior is considered as a physiologic response to systemic inflammation, delirium and consciousness disorders are clinical signs for sepsis-associated encephalopathy. PTSD, posttraumatic stress disorder.

The pathophysiology of SAE comprises neuroinflammation, vascular changes, and metabolic failure. These mechanisms are not homogeneous in the brain and may lead to region-specific focal ischemic or hemorrhagic lesions. Brain centers involved in autonomic control, arousal, awareness, and behavior are affected, accounting for the clinical features of SAE varying from sickness behavior or consciousness impairment ranging from delirium to coma (Fig. 120.1).

Early SAE is characterized by typical metabolic changes on electroencephalogram (EEG), but in more advanced cases, nonconvulsive status epilepticus can be detected in 10% to 15% of cases. Radiologic lesions such as small focal ischemic or edematous lesions can be observed in about 30% of patients with septic shock (Fig. 120.2). The SAE is associated with increased mortality and long-term cognitive impairment affecting memory, attention, verbal fluency, and psychological disorders including depression, anxiety, and posttraumatic stress disorder (see Fig. 120.1). Its management relies mainly on general ICU good practices, especially when SAE leads to coma (see Chapter 19), as specific treatment is still lacking.

FIGURE 120.2 Schematic view of the different pathophysiologic processes observed or supposed during sepsis-associated encephalopathy. Vascular changes include blood-brain barrier (BBB) dysfunction, neurovascular uncoupling, and strokes. Neuroinflammation includes microglial and astrocytic activation enhancing excitotoxicity and metabolic imbalance inducing neuronal cell death.

In contrast to previous beliefs that the brain is an immune-privileged organ, current thinking is that the central nervous system can be profoundly affected by severe systemic infections and the inflammatory response that occurs as a consequence.

EPIDEMIOLOGY

There are 750,000 cases of sepsis per year in the United States, among whom more than 200,000 will die. Sepsis causes or contributes to one-third to one-half of all in-hospital deaths. There is an increasing incidence of sepsis, which is the result of aging and the higher prevalence of chronic diseases and immunocompromised states in the general population.

Because no consensual definition of SAE exists, the reported incidence varies widely across studies. Currently, an encephalopathy in septic patients is detected using scales for coma (ie, the Glasgow Coma Scale) or delirium (ie, the Confusion Assessment Method–Intensive Care Unit, see **Table 11.4**). Sepsis is a major risk factor for delirium and has to be sought in any critically ill patients developing confusion. Delirium and SAE have many risk factors in common, including older age, premorbid neurologic conditions (ie, dementia, Parkinson disease), need for mechanical ventilation, and acute and chronic liver and renal dysfunction. Various antibiotics are potentially neurotoxic and can induce delirium.

Overall, the incidence of SAE varies from 20% to 40% of septic patients admitted to the ICU, reaching up to 70% in elderly mechanically ventilated patients when evaluated by the Confusion Assessment Method–Intensive Care Unit. Similarly, up to 70% of patients with bacteremia have neurologic symptoms ranging from lethargy and mild inattention to coma. The EEG is abnormal in almost 80% of septic patients.

PATHOBIOLOGY

The SAE results from the deleterious effects of systemic inflammation on the brain. The inflammatory signal is mediated through specific pathways to the brain and triggers three nonexclusive processes which are ischemia, neuroinflammation, and cellular metabolic stress. Ischemia results from macro- and microcirculatory dysfunction; neuroinflammation from dysfunction of the vascular complex (ie, endothelial cells, astrocytes, and blood-brain barrier [BBB]) and microglial activation. Cellular metabolic stress is induced not only by these two processes but also other systemic factors (ie, hypoxia, drugs neurotoxicity, dysglycemia, renal or liver failure; see **Fig. 120.1**). These processes lead to mitochondrial dysfunction and oxidative stress, which compromise neuronal function and vitality. Metabolic stress early in SAE may preferentially affect specific brain regions involved in the autonomic and arousal control, behavior response to stress, and cognitive functions such as memory and attention. Experimental studies have consistently showed strong early neuronal activation in the hippocampus, the amygdala, the nucleus tractus solitarii, and the locus coeruleus in the setting of sepsis. Neuropathologic studies of patients who have died from sepsis show increased neuronal apoptosis and microglial activation in human in these specific areas. These findings provide the anatomic substrate of acute and long-term brain dysfunctions (see **Fig. 120.2**).

FIGURE 120.3 Scheme for the response to stress network mobilization during sepsis. The peripheral inflammation signal is transmitted to the central nervous system through three main pathways (*dark blue arrows*) activating specific structures (*light blue arrows*), the circumventricular organs (CVO) or the vagus nerve nuclei. Behavioral, neuroendocrine, and autonomic structures are interconnected and stimulated, leading to the functional response (*dark green arrows* and *rectangles*). BBB, blood-brain barrier.

Brain Signaling

Neural and humoral pathways are physiologically involved in inflammatory signaling to the brain. For instance, vagal afferents can sense intraperitoneal inflammation and convey the information to the medullary autonomic nuclei; vagal nerves are then able to modulate both local inflammation and systemic inflammation (via its splenic innervation). Owing to their connections to other autonomic centers and neuroendocrine and behavior centers, the medullary autonomic nuclei can modulate a broader response to sepsis (**Fig. 120.3**). The humoral pathway involves circumventricular organs and the *area postrema*, which lacks a BBB. They allow trafficking of inflammatory mediators toward the local neuroendocrine and autonomic centers. These two pathways are essential in the orchestration of the response to an inflammatory stress, of which *sickness behavior* is the clinical manifestation. Sickness behavior is a coordinated set of active, adaptive behaviors that help individuals cope with infection, such as sleepiness, malaise, and loss of appetite.

Neuroinflammation and Glial Cell Activation

Microglia are the mononuclear phagocytic cells of the brain and are responsible for immune defense. They are able to phagocyte, migrate, proliferate, and release various mediators. They express a wide variety of receptors, notably to cytokines and pathogen- and damage-associated molecule patterns.

SAE is considered not to be related to direct cerebral infection. Instead, sepsis appears to cause neuroinflammation as a "bystander" effect of the systemic inflammatory response. Sepsis causes microglial activation, which encompasses morphologic, immunologic, and metabolic changes. Microglial activation leads to reactive or amoeboid forms capable of free movement or phagocytosis, a process called *deramification*. These proinflammatory phenotypes are neurotoxic and contribute to pathologic neuronal activation. Through the production of cytokines, nitric oxide, gliotransmitters, and neurotoxic metabolites such as reactive oxygen species, activated microglia increase total neuronal excitability and fuel neuronal hyperactivation. Fragments of living bacteria and bacterial genomic material have been found in the brains of septic animals and humans but without evidence of infectious encephalitis. This suggests the existence of a brain microbiota in the critically ill, which is absent in healthy subjects.

Astrocytes are the most numerous cells in the brain. In addition to controlling BBB permeability and brain-water balance, astrocytes regulate cerebral blood flow via the release of nitric oxide, prostaglandins, and arachidonic acid. Astrocytes express connexins that allow bidirectional exchanges via hemichannels between astrocytes and neurons through the release of "gliotransmitters" in the extracellular milieu. It has been shown that activated microglial cells inhibit gap junction channels and activate hemichannels.

Neuroinflammation is incriminated in dementia of all causes. Indeed, it is hypothesized that a first hit primes microglial cells that will be then overreactive to a second hit. Sepsis can be the primary or the secondary hit. This hypothesis can therefore account for the relationship between the sepsis and cognitive decline as well as the deleterious impact of SAE in patients with preexisting neurodegenerative disease.

Astrocytes and Blood-Brain Barrier Dysfunction

BBB dysfunction occurs in sepsis. The BBB controls the water, molecules, and ions that flow between the blood and the brain and restrains penetration of immune cells, toxins, and pathogens into the brain. The BBB integrity is maintained by astrocytes

and pericytes. Neuropathologic and magnetic resonance imaging (MRI) studies confirm BBB impairment in patients with septic shock, notably by evidencing vasogenic edema involving the white matter. Reports of posterior reversible encephalopathy syndromes (see Chapter 44) in septic patients corroborates these findings.

Ischemic Processes

Brain ischemia can result from either macrocirculatory dysfunction, including hypotension, decreased cerebral flow, and impaired autoregulation, or microcirculatory impairment, encompassing neurovascular uncoupling, BBB disruption, and activation of the coagulation cascade. A postmortem study has shown that ischemic damages were present in all cases of fatal septic shock and were associated to disseminated intravascular coagulopathy-induced hemorrhage in about 20% of these cases. Sepsis is associated with microcirculatory dysfunction that results both in impaired cerebral vascular supply, brain metabolic crisis, and neurovascular uncoupling.

Neurotransmitter Dysfunction

Neurons in sepsis are vulnerable to mitochondrial dysfunction and oxidative stress and excitotoxicity, which is induced by enhanced release and diminished uptake of glutamate in the synaptic space. This neuroinflammatory and ischemic process may be exacerbated by systemic factors such as hypoxemia, electrolyte disorders, dysglycemia, and drug toxicity. Neurotransmitter impairment involves the dopaminergic, β-adrenergic, the γ-aminobutyric acid, and the cholinergic systems. Despite the fact that an imbalance between dopaminergic and cholinergic neurotransmission is incriminated in sepsis-associated delirium, cholinergic drugs, such as rivastigmine, as well as antidopaminergic drugs, such as haloperidol, fail to reduce its occurrence. Benzodiazepines, which are γ-aminobutyric acid agonists, increase the risk of delirium in septic patients for reasons that are unclear.

DIAGNOSIS

Clinical Features

SAE is defined by the association of a systemic infectious or inflammatory process with impairment of brain function, which can range from lethargy to delirium or coma. Focal deficits and seizures can also occur. Sepsis is more frequently associated with a hypoactive than hyperactive delirium. Abnormal movements such as myoclonus, tremor, or asterixis can also be seen. In the ICU, sepsis should be suspected in any critically ill patient who develops a change in mood, behavior, or consciousness, as delirium may be the first sign of infection, particularly in elderly patients.

Brain Imaging

Brain computed tomography (CT) is typically normal in patients with SAE. In about half of septic shock patients, brain MRI shows scattered small regions of edema or infarction, particularly in the white matter. Posterior reversible encephalopathy syndrome has also been reported in septic patients. Given the risk of transporting septic patients, brain CT imaging should be performed for relevant clinical deterioration, including focal neurologic deficit, seizures, or unexplained impaired consciousness. Brain CT scan is easier to perform and may complete a body scan used to identify a source of infection but is less specific and sensitive than MRI. A normal CT in a septic patient with clear evidence of delirium or impaired consciousness points to the diagnosis of SAE. If focal deficits are present despite normal brain imaging, continuous EEG should be performed to rule out associated seizure activity.

Continuous Electroencephalogram Monitoring

Continuous EEG monitoring can assist in the evaluation and management of SAE. Background EEG can be classified as normal or showing predominantly theta, delta, triphasic waves, or suppression. Absence of EEG reactivity to stimuli, triphasic waves, background suppression, and periodic discharges are predictors of delirium and mortality. Seizures of any type can occur in 10% to 15% of septic patients, and nonconvulsive status epilepticus occurs in a subset of these patients. Seizures in SAE almost always occur in the 25% of patients who also have periodic discharges. Nonconvulsive electrographic seizures seem to occur more frequently during periods of active delirium. Clinical tonic-clonic seizures are rare in septic patients. Continuous EEG monitoring has shown that the vast majority of epileptic events occur in the first 48 hours of monitoring. The presence of periodic discharges implies an increased likelihood of detecting electrographic seizures with additional monitoring. Sepsis slightly increases the risk of long-term epilepsy.

MANAGEMENT

The treatment of SAE is fundamentally based on the cornerstones of therapy for sepsis, including rapid diagnosis and timely antibiotic administration, fluid resuscitation directed toward clearing lactate elevation, and blood pressure and ventilatory support. Standard diagnostic studies include CT to rule out a stroke or structural abnormality and continuous EEG monitoring for the detection and treatment of seizures. Pharmacotherapy focuses for the most part on symptom control for agitated delirium or continuous intravenous sedation for ventilator dyssynchrony. There are no established neuroprotective therapies to minimize brain injury and long-term cognitive dysfunction in patients with sepsis. Fever is known to exacerbate neuronal injury and death in the setting of ischemia, making fever control an attractive neuroprotective strategy. Antipyretics have not been shown to influence the outcome of severe sepsis LEVEL 2.[1] A small randomized trial (N = 200) reported decreased vasopressor requirements and improved survival with external cooling to control fever, but the effects on neurologic outcome were not evaluated LEVEL 2.[2]

The most common and well-studied manifestation of SAE is agitated delirium (see also Chapter 11). Delirium is associated with increased mortality and ICU length of stay, and measures should be taken to avoid or minimize delirium in septic patients (Table 120.2). Standard nonpharmacologic interventions for preventing or treating delirium in the ICU include aids to orientation (ie, clock and photos in the room), adequate lighting, avoiding sleep deprivation and noise reduction, early mobilization, minimizing or discontinuing sedation (especially

TABLE 120.2 Strategies to Reduce Brain Dysfunction and Delirium in Sepsis-Associated Encephalopathy[a]

Pharmacologic Measures
• Minimize use of sedation, especially benzodiazepines.
• Perform daily sedation interruption.
• Use dexmedetomidine as the first choice for continuous intravenous sedation.
• Treat pain aggressively using nonsedating, nonsteroidal agents as first-line therapy.
• Treat metabolic disturbances such as hypoxia, hypotension, hyponatremia, and hypoglycemia.
Nonpharmacologic Measures
• Promote normal sleep with quiet times and reduced unnecessary nursing assessments.
• Frequent reorientation and cognitively stimulating activities (ie, conversation)
• Rehydration
• Use of eyeglasses and hearing aids
• Minimize physical restraints.
• Early mobilization

[a]Adapted from Sonneville R, Verdonk F, Rauturier C, et al. Understanding brain dysfunction in sepsis. *Ann Intensive Care*. 2013;3(1):15.

benzodiazepines), and management of physical and psychological discomfort LEVEL 1.[3] Regarding the pharmacologic management of delirium and seizures, no specific sedative agent is proposed by experts, except that sedation should be avoided or discontinued as soon as possible. The α-agonist dexmedetomidine has been shown to lead to more delirium-free days and lower 28-day mortality when compared sedation with lorazepam LEVEL 1.[4] Dexmedetomidine is thought to exert its beneficial effects in part through inhibition of neuronal apoptosis and reduction of the sepsis-associated inflammatory response. Antipsychotic drugs may effectively treat some symptoms of hyperactive or agitated delirium, such as agitation or hallucinations, but are poorly effective in hypoactive delirium. Prior statin use has been associated with reduced risk of delirium in cohort studies of critically ill patients, but a prospective trial of rosuvastatin in patients with sepsis-associated adult respiratory distress syndrome found no effect on the frequency of delirium of on long-term cognitive outcome LEVEL 1.[5] Rivastigmine, a cholinesterase inhibitor that was supposed to control microglial activation, has been shown to increase mortality without reducing delirium in critically ill patients, including septic patients LEVEL 1.[6]

OUTCOME

Impact of Sepsis-Associated Encephalopathy on Survival

There is a proportional relationship between the clinical or electrophysiologic severity of SAE and mortality. Indeed, mortality in sepsis increases from as low as 10% to as high as 70% as the Glasgow Coma Scale decreases from 15 (ie, normal mental status) to below 8, and as EEG progresses from a normal background rhythm to patterns showing generalized periodic discharges, lack of reactivity to stimuli, or electrographic seizures. Coma and delirium are both within the clinical spectrum of SAE, and both are associated with increased risk of death in critically ill patients.

The mechanisms underlying the relationship between SAE and increased mortality has yet to be elucidated. It may be that brain failure is a simple manifestation of generalized multisystem organ failure. It has been hypothesized that sepsis induces brain stem dysfunction that affects both arousal and attention as well as centers that regulate vital functions, such as blood pressure and heart rate, all of which can be compromised in sepsis.

Impact on Sepsis-Associated Encephalopathy on Long-term Outcome

One year after ICU discharge, 25% to 50% of critically ill patients, many who have suffered from sepsis, develop long-term cognitive impairment. Hospitalization for sepsis increases the prevalence of cognitive impairment by 10% over 8 years. Preexisting dementia increases the risk of sepsis, which in turn worsens cognitive status among those who survive. The cognitive functions preferentially impaired by sepsis are attention, verbal fluency, executive function, verbal memory, and speed of mental processing, whereas visual memory and visuoconstructive ability appear to be preserved. Psychological disorders that occur after critical illness, and sepsis in particular, include anxiety, depression, and posttraumatic stress disorder. It has been reported that sepsis increases the risk of suicide in the first 2 years after hospitalization. These psychological and cognitive disorders have a dramatic impact on quality of life and functional status.

Societal Cost of Sepsis-Associated Encephalopathy

Care for patients who develop SAE requires considerable use of ICU resources because it prolongs hospital length of stay. Subsequent long-term psychological and cognitive disorders have created a social-economic burden. Up to 40% of previously employed sepsis survivors have not returned to full-time employment 1 year after the event.

CONCLUSION

SAE is a major complication of sepsis characterized by changes in mental status ranging from sickness behavior to delirium or coma. It is associated with changes of EEG background activity and less frequently with electrographic seizures. It is associated with increased mortality and long-term emotional and neurocognitive disorders. The main mechanisms of injury include neuroinflammatory, ischemic, and excitotoxic processes. Severity of consciousness disorders and EEG changes are predictive of mortality. There is no specific treatment of SAE. Management depends on treatment of sepsis, delirium, seizures, and critical care support for coma.

121 Respiratory Support for Neurologic Diseases

David B. Seder and Stephan A. Mayer

KEY POINTS

1. When respiratory muscle strength is failing, intubation should be performed early to prevent aspiration or respiratory arrest.
2. Noninvasive ventilation is an option for patients with neuromuscular weakness and preservation of cough and airway protective reflexes.
3. Intubation and the initiation of mechanical ventilation can cause changes in cerebral blood flow and intracranial pressure and should be carefully managed.
4. Weaning from mechanical ventilation should occur as soon as possible; when prolonged intubation is anticipated, transition from endotracheal intubation to temporary tracheostomy should be considered.
5. Many patients with respiratory failure due to neurologic disease make an excellent recovery; respiratory failure itself should not be considered a reason to withdraw life-sustaining therapies.

INTRODUCTION

Much of the high morbidity and mortality from acute neurologic disorders results from abnormalities of breathing. Respiratory abnormalities can themselves worsen neurologic injury, whereas neurologic abnormalities conversely predispose to aspiration, impaired airway clearance, atelectasis, and pneumonia. In stroke, traumatic brain injury, status epilepticus, Guillain-Barré syndrome, myasthenia gravis, and many other neurologic disorders, oropharyngeal and respiratory muscle weakness predispose to aspiration of secretions into the airways, mucus plugging, hypoventilation, atelectasis, and pneumonia. Accordingly, respiratory monitoring and support are among the most common indications for the admission of neurologic patients to an intensive care unit (ICU).

EPIDEMIOLOGY

Respiratory failure requiring mechanical support complicates the care of about 10% patients with ischemic stroke and many patients with intracerebral hemorrhage, subarachnoid hemorrhage, severe traumatic brain injury, acute coma or other causes, and severe neuromuscular weakness. Outcomes of patients with respiratory failure due to neurologic disease have improved over the past three to four decades. With up-to-date management, respiratory failure should not pose an independent obstacle to recovery.

PATHOBIOLOGY

Respiratory failure in neurologic disease can be caused by cardiopulmonary failure, such as in the case of a large volume pulmonary aspiration, or more commonly by impaired airway protective reflexes, neuromuscular weakness, or impaired central ventilatory drive. It is useful to for clinicians to understand the nuances of respiratory disease because therapy varies dramatically between patients who can't breathe due to cardiopulmonary respiratory failure or a central apnea syndrome, and those who breathe well but cannot maintain a patent upper airway, which is essential for preventing lower respiratory aspiration and infection.

Pulmonary Gas Exchange

Hypoxemia is characterized by reduced oxygen content of the bloodstream. Hypoxemia is caused by five conditions: (1) a low inspired oxygen concentration, (2) alveolar hypoventilation, or impaired gas exchange within the lungs due to (3) ventilation-perfusion (V/Q) mismatching, (4) transpulmonary or intracardiac right-to-left shunting, or (5) impaired diffusion of gases between the alveoli and the capillaries. It can also be caused by low mixed venous oxygen saturation.

Impaired gas exchange can be quantified by measuring the gradient between the partial pressure of oxygen in the alveoli and the arterial blood (the A/a gradient, which is normally <20 mm Hg) or the P/F ratio, which is the partial pressure of oxygen in the arterial blood (PaO_2, normally 90-100 mm Hg) divided by the fraction of inspired oxygen (FIO_2, normally 21% in room air). Alveolar oxygen tension (PaO_2) can be calculated from the equation $PaO_2 = (FIO_2 \times 713) - (PaCO_2 / 0.8)$, where $PaCO_2$ is the arterial carbon dioxide tension.

The cause of impaired gas exchange leading to hypoxemia can be differentiated according to the response to supplemental oxygen. *Shunting*, defined as hypoxia unresponsive to oxygen supplementation, results from the direct transfer of deoxygenated venous blood into the arterial circulation through an intracardiac atrial septal defect, pulmonary arteriovenous malformation, or perfused but nonventilated lung parenchyma (ie, dense airspace consolidation due to pneumonia). With V/Q mismatching, ventilation and perfusion relationships are heterogeneously deranged, but systemic oxygenation improves in response to a higher FIO_2. Diffusion abnormalities are characterized by abnormalities of the intra-alveolar septae, which may be fibrotic (ie, interstitial lung disease), reduced in number and surface area (ie, emphysema), and inflamed or edematous (ie, acute respiratory distress syndrome, congestive heart failure). Low inhaled FIO_2 is typical of extreme altitude but can also result from equipment malfunction such as rebreathing of exhaled gases.

FIGURE 121.1 Neurogenic respiratory patterns. (Adapted from Plum F, Posner JB. *The Diagnosis of Stupor and Coma*. 3rd ed Philadelphia, PA: FA Davis; 1980.)

Hypercarbia results from impaired alveolar ventilation and is caused by some combination of inadequate "bellows function" of the lung (characterized by reduced minute ventilation, the product of the respiratory rate and tidal volume), increased carbon dioxide production, and impaired gas exchange. Hypoventilation can only be mechanism of hypoxia when concomitant hypercarbia is present (**Fig. 121.1**).

Respiratory Failure

The diagnosis of *respiratory failure* depends on arterial blood gas analysis and on the chronicity of the event. Three separate processes can contribute to the development of respiratory failure: (1) hypoxia, which results from impaired gas exchange in the lung; (2) ventilatory failure, which results from inadequate ability to move air into and out of the lungs; and (3) failure to protect the upper airway, which can result in airflow obstruction or aspiration of secretions, food, or gastric contents.

Chronic respiratory failure is said to be present when a patient cannot maintain adequate oxygenation (Pa_{O_2} >59 mm Hg) or ventilation (P_{CO_2} <50 mm Hg) without supplemental oxygen or ventilatory assistance. In contrast, *acute hypoxemic respiratory failure* describes a state in which adequate oxygenation cannot be maintained despite supplemental oxygen delivery. In these patients, positive pressure ventilation and supplemental oxygen administered through an endotracheal tube (ETT) or by noninvasive positive pressure ventilation (NPPV) are required to maintain normal oxygenation of arterial blood. In the hospital, hypoxemia can be easily and noninvasively diagnosed and monitored by measuring the percentage of oxygen saturation of hemoglobin in the blood (Sp_{O_2}). The clinical hallmark of hypoxemic respiratory failure is cyanosis.

Hypercarbic respiratory failure may be clinically obvious, as seen when the accessory muscles of respiration are activated and the patient appears "working hard to breathe" or can be subtle, manifest only by decreased mental acuity, myoclonus, confusion, agitation, or lethargy. Acute hypercapnia leads to acidosis and cerebral vasodilatation, which in turn can cause depressed level of consciousness ("carbon dioxide narcosis"), aggravation of elevated intracranial pressure (ICP), and blunted respiratory drive, leading to further hypoventilation. Arterial blood gas analysis is the most reliable method for diagnosing hypercarbic respiratory failure, but end-tidal carbon dioxide ($ETCO_2$) monitoring has gained popularity as a noninvasive method to monitor changes in alveolar carbon dioxide tension.

Failure of airway protection is diagnosed clinically when patients appear to be aspirating oral secretions, cannot maintain the upper airway open for gas exchange, have a rapid neurologic decline with a diminished gag and cough reflexes, or are experiencing repeated oxyhemoglobin desaturation due to intermittent plugging of the airways by secretions. Under unstable conditions, such as during a period of acute neurologic instability or during patient transport between hospitals or departments, it is advisable to intubate these patients and start mechanical ventilation to prevent sudden respiratory decompensation. Conversely, it may be safe to extubate such patients later in their hospital

course under controlled circumstances, despite significantly decreased mental status. There is no absolute measure of adequate upper airway protection, and unfortunately, such determinations remain for most part subjective.

The pathophysiology of neuromuscular respiratory failure resembles a vicious cycle. Increased mucus production and/or weak cough leads to mucus plugging and atelectasis, which in turn cause decreased efficiency of ventilation. Hypoxemia usually precedes hypercapnia because atelectasis and V/Q mismatching are an early development. As fever and infection develop, carbon dioxide production increases and ventilatory needs rise. The downward spiral of increasing carbon dioxide production, decreasing efficiency of ventilation, and progressive mucus plugging and atelectasis ultimately results in hypercarbia and respiratory failure. As ventilation fails, rapid shallow breathing and hypercapnia develop. At this stage, ventilatory reserves are exhausted, and there is the danger of sudden life-threatening hypoxemia, respiratory acidosis, or respiratory arrest.

Effects of Respiratory Compromise on Neurologic Injury

Many types of neurologic injury are exacerbated by respiratory compromise. Carbon dioxide and pH are powerful determinants of cerebral vascular tone, and the intended or unintended effects of hyperventilation (decreased cerebral blood flow, decreased intracranial blood volume, and decreased ICP) should be anticipated and monitored by clinicians. Conversely, hypoventilation and hypercapnia cause cerebral vasodilation and increased ICP. Hyperoxia is a potent exacerbant of reperfusion injury, whereas hypoxia is strongly associated with worse outcome in stroke, hypoxic-ischemic encephalopathy, and traumatic brain injury. Finally, when work of breathing is markedly increased, up to 50% of the cardiac output may be diverted to the respiratory muscles, driving metabolic stress, and potentially "stealing" blood flow from the ischemic brain or spinal cord. This metabolic stressor can be effectively managed by sedation, intubation, and initiation of full mechanical ventilatory support.

DIAGNOSIS

Diagnosis of respiratory failure in patients with neurologic disease can often be accomplished by the physical examination, although arterial blood gas analysis, chest imaging, and pulmonary function testing each have an important role to play. These modalities are discussed further below.

Examination

The initial management of the patient with impending respiratory failure is directed toward assessing the adequacy of oxygenation and ventilation, workload and stability of breathing, and assessment of the airway. In patients with fulminant respiratory failure, intubation can be lifesaving and is preferentially performed under safe, controlled circumstances well before the threat of impending cardiopulmonary arrest.

The patient's overall comfort and anxiety levels and the rate of progression of respiratory compromise should be assessed. Hypoxia is usually easy to diagnose with pulse oximetry and arterial blood gas analysis. Hypoventilation and hypercarbia may be present without distress or increased work of breathing if central respiratory drive is compromised, whereas increased respiratory effort with intact respiratory drive manifests as respiratory alkalosis. Sidestream $ETCO_2$ monitoring, less well established than oximetry but effective, is increasingly used to provide early warning of hypoventilation in patients at risk. Rapid, shallow breathing; the use of accessory muscles of the neck and the shoulder; and visible gulping or gasping with inability to generate adequate tidal volumes are signs of respiratory muscle fatigue and impending collapse, although such signs may be absent when central respiratory drive is impaired. Diaphragmatic strength can be estimated by palpating for normal outward movement of the abdomen with inspiration; with severe diaphragmatic paralysis, inspiration is associated with spontaneous inward movement of the diaphragm (abdominal paradox). Activation of respiratory muscles during the expiratory phase often indicates airflow obstruction.

When neuromuscular weakness is present, ventilatory reserves can be assessed by checking the patient's ability to count from 1 to 20 in a single breath. The strength of the patient's cough should be noted. A wet gurgled voice and pooled oropharyngeal secretions are clinical signs of dysphagia and ongoing aspiration. When severe, weakness of the glottic and oropharyngeal muscles can lead to stridor, which indicates possibly life-threatening obstruction of the upper airway.

Dysphagia is assessed by asking the patient to sip 3 oz of water; coughing is diagnostic of aspiration, and if present, oral feeding should be avoided until swallowing can be formally assessed. Patients with decreased cough and gag reflexes, however, may have aspiration without obvious clinical signs. Clinicians should have a low threshold to arrange for formal swallowing evaluation in patients with bulbar dysfunction.

Pulmonary Function Testing

Pulmonary function testing should be routinely used to monitor respiratory function in patients with neuromuscular respiratory compromise (Table 121.1). Arterial blood gases and $ETCO_2$ monitoring are helpful, but abnormalities of gas exchange usually develop later in the cycle of respiratory decompensation and are therefore insensitive for early detection of ventilatory decline. Forced vital capacity, the volume of air exhaled after maximal inspiration and exhalation, normally ranges from 40 to 70 mL/kg. Reduction in vital capacity to 30 mL/kg is associated with a weak cough, accumulation of oropharyngeal secretions, atelectasis, and nocturnal hypoxemia. Forced vital capacity below 15 mL/kg (1 L in a 70-kg person) is the level at which invasive or noninvasive ventilatory support should

TABLE 121.1 Pulmonary Function Tests in Neuromuscular Respiratory Failure[a]

	Normal	Criteria for Intubation and Weaning	Criteria for Extubation
Vital capacity (mL/kg)	40-70	15	25
Maximal inspiratory pressure (cm H_2O)	>80	20	40
Maximal expiratory pressure (cm H_2O)	>140	40	50

[a]Adapted from Mayer SA. Intensive care of the myasthenic patient. *Neurology*. 1997;48(suppl 5):S70-S75.

TABLE 121.2 Criteria[a] for Intubation and Mechanical Ventilation

- Pa_{O_2} <70 mm Hg with maximal oxygen delivery by face mask
- Pa_{CO_2} >50 mm Hg associated with acidosis (pH <7.35), which cannot be rapidly and durably reversed
- Severe oropharyngeal paresis or decreased level of arousal with inability to protect or maintain the airway
- Need for deep sedation or general anesthesia to control seizures or elevated ICP
- Maximal inspiratory pressure <25 cm H_2O or FVC <15 mL/kg
- Respiratory rate >35 breaths per minute or visibly excessive work of breathing

Abbreviations: FVC, forced vital capacity; ICP, intracranial pressure.
[a]These physiologic criteria are intended to serve only as guidelines; treatment decisions must be individualized. As a general rule, intubation in neurologic patients with impending respiratory failure should be performed *before* significant blood gas abnormalities develop.

be considered (**Table 121.2**). Maximal inspiratory pressure, normally more than 80 cm H_2O, measures the strength of the diaphragm and other muscles of inspiration and generally reflects the ability to maintain normal lung expansion and avoid atelectasis, whereas maximal expiratory pressure, normally more than 140 cm H_2O, measures the strength of the muscles of expiration and correlates with cough and the ability to clear secretions from the airway.

Blood Gas Analysis and Monitoring

Although transcutaneous monitoring of oxyhemoglobin saturation is standard, pulse oximetry alone is often inadequate to detect impending ventilatory failure because hypoxia occurs as a late event. Arterial blood gas analysis remains the gold standard for determining the partial pressure of oxygen and carbon dioxide in the blood and should be obtained when respiratory function is compromised. Thoughtful interpretation of blood gas results is also critical to reveal respiratory and metabolic acidosis or alkalosis and the extent to which these derangements have been compensated. In acute ventilatory failure, the pH is expected to drop by 0.08 units and bicarbonate to rise by 1 mEq/L for every 10 mm Hg rise in P_{CO_2}, whereas in chronic respiratory acidosis, the pH drops by 0.03 units and bicarbonate rises by 3 to 4 mEq/L for every 10-point rise in P_{CO_2}. Respiratory alkalosis can be caused by pain or anxiety but is also common in primary central nervous system injury. Central hyperventilation may suggest not only brainstem dysfunction but also elevated ICP, an unbuffered intracranial acid load, or pressure on the floor of the fourth ventricle. Arterial blood gas analysis is important in detection of carboxyhemoglobin, when carbon monoxide poisoning is suspected, and of methemoglobinemia.

Capnography ($ETCO_2$ monitoring) is useful in both intubated and nonintubated patients to monitor changes in ventilation and is particularly important for patients with elevated ICP, for whom acute changes in carbon dioxide tension can result in dramatic changes in cerebral blood flow and ICP. Capnography does not take the place of an arterial blood gas and is best interpreted in terms of its relationship to P_{CO_2}, which varies among patients and over time.

MANAGEMENT OF RESPIRATORY FAILURE

Noninvasive Positive Pressure Ventilation

Mechanical ventilatory support is the primary treatment of respiratory failure. If airway protection is adequate and the patient is relatively cooperative, NPPV administered via a snug-fitting facemask should be considered. In medical patients with an acute exacerbation or chronic obstructive pulmonary disease or congestive heart failure, NPPV has fewer complications than invasive mechanical ventilation LEVEL 1.[1] In neurologic patients, the use of NPPV is becoming increasingly common as an initial intervention for early neuromuscular respiratory failure from myasthenic exacerbation and in others with chronic neuromuscular weakness and acute respiratory disease. Its use in Guillain-Barré syndrome is controversial, however, with mixed results and some concerns about safety due to the potential for respiratory arrest.

Among patients with neuromuscular weakness, early use of NPPV maintains lung expansion, reduces the work of breathing, and minimizes the risk of severe respiratory failure requiring intubation. Only patients with adequate airway protective reflexes should be treated, and NPPV should *not* be used as a substitute for endotracheal intubation when acute respiratory failure is severe or complete elimination of the work of breathing is desirable. Noninvasive ventilation requires close observation in a monitored setting and the availability of rapid intubation in the event of respiratory decompensation. Many clinicians prefer the security of invasive mechanical ventilation with an ETT or a tracheostomy, but neurologists should be aware that in ICUs where high-quality, safe NPPV can be provided; it is often strongly preferred by patients and reduces the incidence of hospital-acquired infections, the need for sedation and analgesia, and the length of ICU stay. Noninvasive ventilation should be used in conjunction with mechanical cough assist devices to aid in airway clearance—a combination that effectively treats mucus plugging and atelectasis and keeps many patients off the ventilator.

Endotracheal Intubation and Mechanical Ventilation

Indications for endotracheal intubation due to respiratory failure may include compromised ventilation or oxygenation, the need for airway protection, or both. For patients needing endotracheal intubation, clinicians should consider the patient's comfort level as well as intracranial and arterial pressures. Intravenous (IV) access should be obtained prior to intubation and infusion because sedation and positive pressure ventilation may cause a precipitous drop in blood pressure. All patients should be preoxygenated with an F_{IO_2} of 100% prior to intubation, and in patients with elevated ICP, mild hyperventilation should be considered before lowering the head of the bed and extra efforts made to avoid hypoventilation.

Special concerns related to the intubation of neurologic patients are described in **Table 121.3**.

The administration of 50 to 100 mg of IV lidocaine immediately before intubation blunts the anticipated rise in ICP. *Rapid sequence intubation* involves administration of a combination of IV sedatives (ie, etomidate or fentanyl), amnestics (ie, midazolam), and muscle relaxants (ie, vecuronium); depolarizing

TABLE 121.3 Intubation and Respiratory Concerns Specific to Patients With Neurologic Disease

Problem	Assessment	Management
Elevated ICP	Mass lesion, cerebral edema, hydrocephalus	Preadministration of mannitol or hypertonic saline solution, minimize head-flat positioning, adequate analgesia and sedation, avoidance of hypoventilation
Brain ischemia	Acute stroke with penumbra	Administration of fluids and/or vasopressors, avoidance of vasodilators, $ETCO_2$ monitoring, avoidance of hyperventilation
Cervical spine injury or instability	Mechanism of injury suggesting cervical spine injury or radiographic injury	In-line spinal stabilization; intubation techniques to minimize anteroposterior cord displacement
Ischemia-reperfusion injury	Minimize biochemical harm	Normalize oxygenation (keep Pa_{O_2} 60-300 mm Hg) and ventilation (keep Pa_{CO_2} 30-50 mm Hg or $ETCO_2$ 30-45 mm Hg)

Abbreviations: $ETCO_2$, end-tidal carbon dioxide; ICP, intracranial pressure.

muscle relaxants such as succinylcholine should be avoided in patients suffering from immobility or paresis because of a possibly abrupt rise in serum potassium level after drug-induced muscle depolarization. The trachea may be intubated orally or nasally; a high-volume, low-pressure cuff is then inflated in the trachea to prevent leakage of air and secretions around the tube.

Modes of mechanical ventilatory support include volume- and pressure-cycled ventilation, pressure support with continuous positive airway pressure (CPAP), and many others (Table 121.4). Although no ventilatory mode is intrinsically superior to the others, in general, patients should be ventilated according to the basic principles of lung-protective ventilation to avoid ventilator-induced lung injury in the setting of acute lung injury or acute respiratory distress syndrome LEVEL 1.[2] Lung-protective ventilation endeavors to minimize barotrauma and volutrauma due to overdistention of aerated lung segments, trauma from atelectasis due to repetitive opening and closing of collapsed alveoli, and biotrauma due to inflammation. This is accomplished by minimizing peak and plateau airway pressures (goal <30 cm H_2O), providing positive end-expiratory pressure (PEEP) to prevent alveolar collapse at end-expiration and to recruit collapsed lung units, limiting exposure to toxic levels of oxygen and using small tidal volumes (4-6 mL/kg of *ideal* body weight) to prevent overdistention of vulnerable alveolar units LEVEL 1.[2] More recently, it has been shown that maintaining *driving pressure*—the plateau airway pressure minus PEEP—below 14 mm Hg is associated with reduced mortality in the setting of acute respiratory distress syndrome. In general, "permissive" hypercapnia and hypoxia—part of most lung protective ventilation protocols—should be employed cautiously and after consideration of the effects of dysventilation on neurophysiology. Unless required for control of elevated ICP, prolonged uninterrupted deep sedation and paralysis are discouraged because spontaneous respiratory efforts by the patient prevent dependent atelectasis and respiratory muscle atrophy.

TABLE 121.4 Ventilator Modes and Functions

Abbreviation	Stands for Description
SIMV	Synchronized intermittent mandatory ventilation
CMV	Continuous mandatory ventilation
PS	Pressure support
CPAP	Continuous positive airway pressure
PEEP	Positive end-expiratory pressure

Manipulation of Ventilation: Effects on Intracranial Pressure and Cerebral Blood Flow

Hyperventilation results in acute hypocarbia and respiratory alkalosis. This causes arteriolar constriction in the brain, leading immediately to decreased cerebral blood flow and lower ICP. Conversely, hypoventilation results in hypercarbia and cerebral arteriolar dilation, causing increased cerebral blood flow and ICP. These physiologic responses are frequently manipulated to treat elevations of ICP and because of the potential for harm should be carefully monitored in patients with impaired cerebral perfusion or elevated ICP.

Hyperventilation is a powerful tool to reverse critical increases in ICP and is a standard measure to reverse uncal or transtentorial herniation syndromes. The negative effects of hyperventilation on cerebral blood flow prohibit prolonged and excessive usage unless brain tissue oxygenation is concurrently monitored. Hyperventilation should not be used at all when active brain ischemia is present such as in acute large-vessel stroke or cerebral vasospasm. In addition to the danger of precipitating brain ischemia, prolonged hyperventilation is rarely effective as a treatment for elevated ICP, as compensatory mechanisms in the central nervous system rapidly buffer the pH changes in peripheral pH, and cerebral blood flow is restored. Hyperventilation below a P_{CO_2} of 20 mm Hg causes progressive hemodynamic deterioration but does not result in additional arterial constriction or reduction in ICP. It is not known whether spontaneous hyperventilation puts the brain at risk for ischemia or whether it simply reflects a physiologic compensatory mechanism at work.

$ETCO_2$ tension correlates modestly well with the partial pressure of alveolar carbon dioxide, and in-line $ETCO_2$ can be monitored as a continuous vital sign in mechanically ventilated patients, whereas sidestream $ETCO_2$ is used to monitor alveolar carbon dioxide tension in nonintubated patients. $ETCO_2$ tends to run slightly lower than arterial P_{CO_2}; differences between the two measurements reflect not only dead space ventilation but also increasing age, chronic obstructive pulmonary disease, and circumstances in which alveolar dead space increases such as hypovolemia, pulmonary embolism, and a low cardiac output state.

Prevention of Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is the most common and serious complication of endotracheal intubation. The ETT serves as a conduit for bacterial invasion of the airway and deep

TABLE 121.5 Contraindications to a Daily Spontaneous Breathing Trial

• FIO_2 >80%, PEEP >10 cm H_2O, or high risk of lung derecruitment in severe ARDS
• Deep sedation or paralysis for control of seizures, ICP, or shivering
• Active and clinically important brain or myocardial ischemia
• Severe and unstable cerebral vasospasm

Abbreviations: ARDS, acute respiratory distress syndrome; FIO_2, fraction of inspired oxygen; ICP, intracranial pressure; PEEP, positive end-expiratory pressure.

lung segments and compromises natural defenses against infection. About 20% of patients who are intubated for more than 1 week develop VAP, which adds an average of 1 week to the ICU length of stay, $40,000 to the cost of care, and carries an attributable mortality exceeding 30%. The clinical diagnosis is established by the appearance of a new pulmonary infiltrate on chest radiography more than 48 hours after intubation and the new onset of fever, leukocytosis, or purulent secretions. Neurologic patients are at particularly high risk for VAP because they are immobile and tend to aspirate.

A standardized protocol of measures that minimize bacterial colonization of the upper airway and digestive tract and the risk of aspiration can reduce the risk of VAP. These measures include 30° head elevation to minimize gastric regurgitation, mouth care with chlorhexidine-based solutions, avoidance of unnecessary antibiotics, and removal of the ETT as soon as possible by combining daily interruption of sedation with spontaneous breathing trials (SBTs) LEVEL 1.[3] Some ICUs employ selective gut decontamination or prophylactic antibiotics in patients with neurologic disease to decrease the incidence of respiratory infections, but these measures are not widely recommended and require further study.

Weaning From Mechanical Ventilation

Weaning from mechanical ventilation is a continuous process that should begin as soon as a moderate level of medical and respiratory stability is achieved. Although excessive work of breathing should be avoided as a stressor in patients with neurologic or cardiac ischemia, respiratory work is necessary to prevent muscle atrophy, and the duration of mechanical ventilation is strongly correlated with the development of VAP and other medical complications. Ventilator weaning should be delayed in only dire circumstances (**Table 121.5**). A typical weaning protocol is shown in **Figure 121.2**.

Weaning of mechanical ventilation begins with the lightening of sedation, downward titration of FIO_2 and mean airway pressure to levels consistent with spontaneous ventilation, and face mask oxygen delivery. This is typically consistent with an FIO_2 of 40% and PEEP of 5 cm H_2O. Compared to gradually reducing the respiratory rate using synchronized mandatory ventilation or the level of pressure support triggered by each breath, the best results are obtained through the use of daily SBTs. SBTs vary widely in design but reflect a measured period of breathing in which most or all of the work of breathing is performed by the patient and after which a protocolized assessment is performed to determine suitability for the discontinuation of mechanical ventilation. The most common types of SBTs involve placing the patient on CPAP with a low-level pressure support (usually 5 cm H_2O) sufficient to overcome ETT resistance and T-piece trials, in which the patient breathes spontaneously for a predetermined duration through an open tubing system with flow-by oxygen.

The ability of the patient to tolerate a T-piece or CPAP trial for 2 hours, while maintaining a ratio of respiratory rate (breaths per minute) to tidal volume (liters) less than 100, is a useful predictor of successful extubation. In patients with depressed level of consciousness or neuromuscular respiratory weakness, the ability to tolerate a T-piece or CPAP ventilation overnight offers additional reassurance that the patient has adequate stamina

FIGURE 121.2 Ventilator weaning protocol. Abbreviations: AC, assist control; ICP, intracranial pressure; PEEP, positive end-expiratory pressure; SBT, spontaneous breathing trial.

TABLE 121.6 General Criteria for Extubation

• Successful completion of a spontaneous breathing trial
• Neurologic and medical condition is stable or improving.
• Cough and gag reflexes present, minimal pooling of secretions
• Pa_{O_2} >70 mm Hg with 40% oxygen and PEEP ≤8 cm H_2O
• Minute ventilation <12 L/min at rest
• Vital capacity >15 mL/kg and maximal inspiratory pressure >25 mm Hg
• No pending procedures, operations, or radiographic studies requiring airway protection
• Minimal secretions or moderate secretions with strong cough
• Volume status optimized, airway reactivity assessed and treated, feeds held
• Equipment, medications, and personnel necessary for reintubation readily available

Abbreviation: PEEP, positive end-expiratory pressure.

to tolerate breathing off the ventilator indefinitely. Indications of tiring during an SBT include an increasing respiratory rate with decreasing tidal volumes, a drop in arterial oxygen saturation, diaphoresis, the progressive use of accessory muscles of respiration, or hemodynamic instability. Failure of a weaning trial is a physiologic stressor, and patients with these signs should be returned to mechanical ventilation.

In patients with tracheostomy or receiving NPPV, detachment from and reconnection to the ventilator is uneventful and easy to perform. Extubation and reintubation, however, always entail risk. Before a planned extubation, the patient's volume status, airway reactivity, secretions, and cardiac function should be optimized (Table 121.6). Despite the best predictors of successful extubation, it is not possible to evaluate the airway itself prior to extubation. Even with careful patient selection and medical optimization, as many as 20% of extubated patients are reintubated within 48 hours, and patients with neurologic diseases are among the most difficult to predict.

Tracheostomy

Clinicians have traditionally performed tracheostomy when mechanical ventilation has been used for more than 14 days. Tracheostomy has several advantages over prolonged endotracheal intubation, including increased comfort, reduced risk of permanent tracheolaryngeal injury, increased ease of weaning from the ventilator (reduced dead space and less resistance to flow from the ETT), and improved ability to manage and suction secretions. In comatose patients or in those with profound neuromuscular weakness for whom a prolonged period of ventilator dependence is anticipated, early tracheostomy within 3 to 5 days of intubation extends these benefits and has been associated with reduced ICU length of stay and mortality. Most patients with significant bulbar dysfunction following an acute brain injury will require tracheostomy for secretions management, although they can often be weaned rapidly from mechanical ventilation, and many will ultimately be decannulated when cough strength and airway protective reflexes have partially recovered.

Percutaneous tracheostomy creates a temporary stoma that is easily and rapidly reversible upon decannulation, whereas surgical tracheostomy creates a more durable and permanent stoma that typically requires surgical closure. In some patients with severe persistent oropharyngeal muscle weakness, a tracheostomy is necessary to manage secretions and prevent aspiration, even though respiratory muscle function is adequate.

Long-Term Ventilation

In chronic respiratory failure, patients and clinicians should work together to determine the best interface for mechanical ventilatory support. Patients with good bulbar function and normal level of consciousness can often tolerate intermittent daytime and continuous nocturnal NPPV by nasal or face mask, whereas those at high risk for aspiration, or with a low or waxing and waning level of arousal, are more safely ventilated by tracheostomy. Patients with CRF often describe improved quality of life with NPPV and may be at lower risk of developing respiratory infections than patients with permanent tracheostomy—this has been dramatically demonstrated in patients with respiratory failure due to progressive Duchenne muscular dystrophy. Yet, patients with a tracheostomy can sometimes speak and eat; an experienced speech therapist can determine the safety of and capacity for these activities. Adjustments in tidal volume and tracheostomy size may be important in facilitating speech, and cuff deflation dramatically improves the ability to speak and swallow but leaves the airway open to aspiration.

Some patients need ventilatory support for months or years. Small suitcase- or laptop-sized ventilators are available for use at home, and battery-powered portable ventilators can allow wheelchair-bound patients to travel out of the home. For patients with respiratory failure after brainstem or high cervical cord lesions, an implantable phrenic nerve pacemaker can be used to stimulate diaphragmatic contraction, liberating the patient from connection to a machine.

OUTCOMES

At one time, neurologic and particularly cerebrovascular patients requiring mechanical ventilation had a very poor prognosis, and the usefulness of life support in the neurocritically ill was a topic of controversy. Mechanical ventilation was seen as an indicator of illness severity, and its application were rarely described. Today, with improved medical and surgical therapies for cerebrovascular disease, improved mechanical ventilation and general ICU practices, more sophisticated prevention of secondary neurologic injury, and dedicated treatment in specialized neurologic ICUs, outcomes of mechanically ventilated patients with neurologic disease have improved. As accurate prognostication can rarely be performed in the hours after presentation to the medical care system, airway and respiratory management must be initiated to prevent secondary brain injury during the stabilization phase of care, and neurologists should be prepared to provide respiratory support.

Endocrine Diseases and the Brain 122

Spyridoula Tsetsou and Alexandra S. Reynolds

KEY POINTS

1. Pituitary disorders can cause symptoms related to lack or excess of hormones but can also result in direct compressive effects on nearby cranial nerves.
2. Obtaining thyroid-stimulating hormone and free thyroxine levels can help determine etiologies of hyperthyroidism and hypothyroidism.
3. Glycemic control is critical to minimizing occurrence or progression of neuropathy and macrovascular complications.

INTRODUCTION

Endocrine secretions and disorders of metabolism have a profound influence on the nervous system. Disturbances of consciousness and cognition along with a variety of other neurologic symptoms may accompany primary endocrine diseases (Table 122.1). This chapter considers common endocrine conditions that may cause important neurologic symptoms.

PITUITARY DISORDERS

The pituitary gland is located in the sella turcica and is divided into anterior and posterior lobes. The hypothalamus generates both the anterior and posterior lobes' hormone secretion and production (Fig. 122.1). The anterior pituitary produces and releases adrenocorticotropin or corticotropin (adrenocorticotropic hormone [ACTH]), follicle-stimulating hormone (FSH) and luteinizing hormone (LH), growth hormone (GH), prolactin, and thyroid-stimulating hormone (TSH), whereas the posterior pituitary stores and releases antidiuretic hormone (ADH) or vasopressin, and oxytocin. Stimulatory or inhibitory hormones produced by the hypothalamus (in the paraventricular and arcuate nuclei) stimulate the release of anterior pituitary hormones, which in turn stimulates hormone production at the target organ. Neurosecretory cells from the hypothalamus produce ADH and oxytocin, which are then transported and stored in the posterior pituitary.

Pituitary disorders manifest with a variety of systemic and neurologic symptoms related to either lack or excess of hormones. The pituitary's anatomic proximity with cranial nerves and the cavernous sinus (Fig. 122.2) is responsible of visual field defects (particularly bitemporal hemianopia), ophthalmoplegia, cerebrospinal fluid leak, and cavernous sinus infiltration with certain pathologies. The more common pituitary disorders are described in this chapter.

TABLE 122.1 Prevalence and Incidence of the Most Common Endocrine Diseases

Disease	Incidence	Prevalence
Hypopituitarism	4.2/100,000	45.5/100,000
Cushing disease	2-3/1,000,000	Not reported
Hypothyroidism	0.65-4.57/1,000	1-5/100
Hyperthyroidism	Not reported	0.5-1.3/100
Diabetes mellitus	6.7/1,000	9.4/100
Adrenal insufficiency	4.4-6/1,000,000	150-280/1,000,000
Cushing syndrome	0.2-5/1,000,000	40/1,000,000
Pheochromocytoma	0.005-0.1/100	1/2,500-1/6,500
Hypoparathyroidism	37/100,000	1/60,000-80,000
Hyperparathyroidism	22/100,000	1-7/1,000

Hypopituitarism

Epidemiology

Limited data are available for the epidemiology of hypopituitarism. In one population-based study from Spain, its prevalence was 45.5 cases per 100,000 with an incidence of 4.2 cases per 100,000 per year.

Pathobiology

Hypopituitarism is defined as a deficiency in one or more pituitary hormones. It can be caused by mechanical, vascular, or neural disconnection from the hypothalamus as is seen in direct damage (tumor, radiation), inflammatory processes (lymphocytic hypophysitis/infundibulitis, sarcoidosis, Langerhans cell histiocytosis, Wegener granulomatosis), infectious diseases (tuberculosis, postsurgical bacterial or fungal abscess formation, rarely syphilis or parasites), trauma, subarachnoid hemorrhage, severe hypotension or shock, empty sella syndrome, or occlusive spasm of pituitary arteries with anoxic-ischemic necrosis (apoplexy) of a pituitary gland that has hypertrophied (usually under estrogen stimulation from pregnancy, known as *Sheehan syndrome*).

Clinical Features, Diagnosis, and Treatment

ACTH Deficiency

ACTH deficiency will lead to cortisol deficiency and secondary adrenal insufficiency. Symptoms are nonspecific and include weight loss, fatigue, weakness, nausea, and orthostatic hypotension. A morning (6:00-8:00) serum cortisol greater than 18 μg/dL usually reflects an intact hypothalamic-ACTH-adrenal axis. In case of lower levels, a confirmatory test such as an ACTH stimulation test or an insulin tolerance test is required for diagnosis. However, these tests are mainly useful in chronic pathology and can falsely suggest secondary adrenal insufficiency in acute hypothalamic or pituitary injury. The gold standard treatment consists of glucocorticoid replacement, typically with hydrocortisone 15 to 25 mg/d or prednisone 4 to 7.5 mg/d. Dexamethasone should be avoided due to its long

FIGURE 122.1 Hypothalamic-pituitary-target organ axis. Abbreviations: ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHIH, growth hormone-inhibiting hormone (also known as somatostatin); GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; IGFs, insulin-like growth factors; LH, luteinizing hormone; PIH, prolactin-inhibiting factor; PRH, prolactin-releasing hormone; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone. (Image from Carvalho K, Grunwald T, De Luca F. Neurological complications of endocrine disease. *Semin Pediatr Neurol.* 2017;24:33-42.)

and nonphysiologic half-life; however, if it is prescribed (eg, in postneurosurgical patients), it should not be combined with prednisone or hydrocortisone.

FSH and LH Deficiency

FSH and LH deficiency will manifest as hypogonadism with oligomenorrhea or amenorrhea and impaired ovulation in females as well as decreased libido, decreased bone density, vaginal atrophy, and thin skin. In males, primary symptoms consist of decreased libido, low sperm count, erectile dysfunction, fatigue, and decreased bone density. Female hypogonadism in premenopausal women is diagnosed by low estradiol and low to normal luteinizing hormone and follicle-stimulating hormone, and is treated with estrogen and progesterone (oral, intramuscular, or transdermal). Male hypogonadism is confirmed with low morning testosterone levels and is treated with testosterone preparation (transdermal gel, patch, or intramuscular), with frequent prostate-specific antigen monitoring. Gonadotropins may be necessary for both women and men who desire fertility.

GH Deficiency

GH deficiency in adults causes thin and dry skin, weight gain (especially around the waist), muscle atrophy, fatigue, low energy, decreased exercise tolerance and strength, and mood disorders (depression, anxiety). Diagnosis requires pituitary stimulation testing (with arginine, GH-releasing hormone or insulin-induced hypoglycemia) or documented lack of three or more anterior pituitary hormones with decreased serum insulin-like growth factor 1 (IGF-1). Treatment consists of GH replacement; however, dosing is not well established in adults.

Prolactin Deficiency

Prolactin deficiency is clinically evident in cases of insufficient postpartum lactation.

TSH Deficiency

TSH deficiency will lead to a decrease in free levothyroxine (free T_4) production, with concomitant fatigue, cold intolerance, dry

FIGURE 122.2 Pituitary sella, pituitary gland anatomy. Abbreviation: CN, cranial nerve. (Image from Utz LA, Klibanski A. Pituitary disorders. *Continuum Lifelong Learning Neurol.* 2009;15[2]:17-36.)

skin, weight gain, constipation, and mood disorders. TSH levels can sometimes be in the normal range, and free T_4 measurement is crucial for the diagnosis of central hypothyroidism when clinically suspected. Treatment consists of levothyroxine replacement.

ADH Deficiency (Diabetes Insipidus)

ADH deficiency in response to serum hyperosmolar stimuli leads to diabetes insipidus (DI). Diagnosis requires the presence of polyuria, dilute urine, and increased serum sodium level, in the setting of suspected pituitary injury. If increased water intake cannot balance the excessive fluid losses and correct the serum sodium levels, administration of desmopressin should be the next step (intravenous, intranasal, or oral).

Hyperpituitarism

Epidemiology

There is no data about the incidence of hyperpituitarism. Specific hormone excess condition incidences are referred in the following text.

Pathobiology

Excess of one or more pituitary gland hormones defines hyperpituitarism. It is usually related to primary or metastatic secretory tumors, traumatic brain injury, or specific medications. Multiple endocrine neoplasia type 1 is a syndrome consisting of pituitary adenoma with pancreatic endocrine tumors and parathyroid tumors.

Clinical Features, Diagnosis, and Treatment

Hyperprolactinemia

Hyperprolactinemia (prolactin excess) is mainly associated with prolactinomas, the most frequent functional pituitary tumor. Craniopharyngiomas and traumatic brain injury are other less frequent causes. Specific medications (antipsychotic drugs, opioids, metoclopramide, and antidepressants) as well as hypothyroidism, anorexia nervosa, polycystic ovarian syndrome, and rarely a postictal state may be associated with mild hyperprolactinemia. "Stalk effect" can also lead to mild increase in serum prolactin; this occurs as a result of any infiltrative lesion in the hypothalamus, infundibulum, or sella that impairs the inhibitory dopamine pathway. Women mainly present with galactorrhea, infertility, amenorrhea, and loss of libido. Men present with low fertility and low sperm count, impotence, loss of libido, and breast enlargement. Basal prolactin levels greater than 200 ng/mL are associated with prolactinomas and require a further workup with brain magnetic resonance imaging (MRI). Initial management consists of ergot-derived dopamine receptor agonists (bromocriptine and cabergoline), followed by surgery if there is no improvement or a progression of symptoms.

Hypercortisolism (Cushing Disease)

Cushing disease is caused by excessive ACTH production, with a reported global incidence of 2 to 3 cases per 1,000,000 inhabitants. Approximately two-thirds of cases are related to pituitary adenomas, whereas the remaining ones are due to ectopic ACTH production. Central obesity, buffalo hump, striae, muscle wasting, excessive bruising, hypertension, glucose intolerance, menstrual irregularities, and mood disorders (psychosis, depression, anxiety) are the main associated clinical symptoms. Diagnosis is based on the identification of clinical signs of hypercortisolism, establishment of hypercortisolemia (either with 24-h urine cortisol measurement, 11 PM to midnight salivary cortisol levels, or 1 mg dexamethasone suppression testing) followed by clarification of ACTH dependent/independent production. If ectopic ACTH production is suspected, the determination of the source should be the next step. Treatment consists of surgical resection.

GH Excess

GH excess in adults leads to acromegaly. This typically includes overgrowth of flat bones, and particularly, the mandible with subsequent prognathism, as well as of feet bones with increases in shoe size. Skin tags, cardiomyopathy, peripheral neuropathy, carpal tunnel syndrome, macroglossia, glucose intolerance, and fatigue are some common symptoms. Increased IGF-1 accompanies GH excess. Oral glucose suppression tests (positive if 75-g glucose load fails to suppress GH levels <2 mU/L in the following 2 h) can be useful for borderline cases. A random GH of less than 0.4 μg/L (<1 mU/L) with normal IGF-1 typically excludes active disease. Somatostatin analogues are the first choice of treatment, followed by surgical management and, rarely, radiation. Dopamine agonists and GH-receptor antagonists can also be effective.

TSH Excess

TSH excess related to a TSH-secreting pituitary adenoma is a very rare condition, with an annual incidence reported in a Swedish study of 0.15 cases per 1,000,000 inhabitants. Cosecretion of GH or prolactin is common in these cases. High serum TSH with high free and total T_4 and triiodothyronine (T_3) are diagnostic of secondary hyperthyroidism. A thyrotropin-releasing hormone (TRH) test can be used as a confirmatory study. Somatostatin analogues may be effective. Surgery is indicated for failure of improvement or symptom progression. Antithyroid drugs are contraindicated.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Syndrome of inappropriate ADH (SIADH) secretion due to excessive ADH (vasopressin) production can be related to either intracranial or extracranial pathology. Symptoms vary, from mild headaches to severe confusion, focal deficits, seizures, and death. Excess ADH release results in retention of free water causing hypotonic, euvolemic hyponatremia (sodium <135 mEq/L). Serum osmolality is usually low (<280 mOsm/kg) and urine osmolality is high (>100 mOsm). Urine sodium concentration can vary depending on sodium intake but is usually more than 40 mEq/L. Treatment consists of fluid restriction for sodium correction. Resistant cases may require administration of vasopressin-receptor antagonists. Rapid sodium correction should be avoided (except in acutely, severely symptomatic patients) due to a high risk of central pontine and extrapontine) myelinolysis.

Pituitary Tumors

Pituitary tumors can be asymptomatic or can cause symptoms related to space-occupying effects such as headaches, visual field defects, cavernous sinus infiltration, cerebrospinal fluid leak, and rarely seizures. Symptoms of hypopituitarism (through direct damage) or hyperpituitarism (due to hormone-secreting tumors) can also be present.

Pituitary Adenomas

Typically, these arise from the anterior pituitary and are the most frequent pituitary tumors. Older studies estimated that 10% to 20% of individuals have a pituitary adenoma. They are classified

on functional (if hormones are produced) or nonfunctional. Functional adenomas make up 60% to 85% of all pituitary adenomas. Adenomas are also classified according to their size; macroadenomas are greater than 1 cm in diameter, whereas microadenomas are less than 1 cm. On MRI, adenomas appear isointense on T1 sequences without gadolinium and hypointense on T1 postgadolinium (Fig. 122.3A-C). Treatment depends on symptoms and the size of the adenoma. Conservative medical management with pharmacologic agents is indicated in some types (as discussed earlier); however in case of failure, surgery should be considered. Radiation therapy can also be an option, with the risk of subsequent hypopituitarism and further tissue damage.

Prolactinoma

Prolactinomas make up 40% to 50% of anterior pituitary adenomas and of 40% of all pituitary tumors. They arise from lactotroph cells and produce prolactin excess leading to hyperprolactinemia, with symptoms as described earlier. Initial treatment consists of ergot-derived dopamine receptor agonists (bromocriptine and cabergoline) with surgery reserved in case of drug failure or for patients unable to tolerate dopamine agonists.

Corticotropin-Producing Adenoma

Corticotropin-producing adenomas result in hypercortisolism (Cushing disease). They represent 10% to 15% of pituitary adenomas. Symptoms and diagnosis are described earlier. Random cortisol levels have no value in Cushing disease diagnosis.

Growth Hormone-Secreting Adenoma

GH-secreting adenomas, which comprise 10% to 20% of pituitary adenomas, lead to acromegaly in adults, with typical symptoms as described earlier in the chapter.

Thyrotropin-Secreting Adenoma

Thyrotropin-secreting adenomas are extremely rare and represent approximately 1% of pituitary adenomas. They are the main cause of hyperthyroidism without TSH suppression.

Other Pituitary Tumors

Craniopharyngioma

Craniopharyngiomas arise from epithelial and squamous cell remnants of the craniopharyngeal duct. They are usually benign and are multicystic and calcified appearance (Fig. 122.3D-F). They tend to peak in childhood (at around the age of 9 y old) and then in adulthood (in late middle age). Symptoms result from space-occupying effects, and sometimes, DI can occur. Children may experience growth deceleration. Surgery remains the gold standard treatment. Cases of partial resection may be followed by radiation due to high risk of recurrence.

Metastatic Pituitary Tumor

Metastatic pituitary tumors are rare, with lung and breast being the most frequent primary cancers. They are characterized by rapid growth and radiologically are most often contrast enhancing. They are frequently associated with DI and cranial nerve palsies.

Other Pituitary Disorders

Pituitary Apoplexy

Pituitary apoplexy is a neurologic emergency and is caused by acute hemorrhage or infarction in pituitary sella, usually in the setting of a preexisting adenoma. Pituitary infarction is also described in peripartum or postpartum period and is associated with severe hypotension or massive blood loss.

FIGURE 122.3 Magnetic resonance imaging of pituitary adenoma **(A-C)** and craniopharyngioma **(D-F)**. Coronal view, T1, without contrast **(A)** and coronal view, T1, postgadolinium showing pituitary tumor abutting the optic chiasm **(B)** *(arrows)*. C: Sagittal view, T1, postgadolinium. Coronal view, T1, without contrast **(D)** and coronal view, T1, postgadolinium showing cystic component of craniopharyngioma **(E)**. F: Sagittal view, T1, postgadolinium.

Typical symptoms include acute onset headaches, bitemporal hemianopia, ophthalmoplegia, DI or SIADH secretion, and hypopituitarism. Half of cases will not be evident on computed tomography, and diagnosis is most often confirmed by the presence of pituitary hemorrhage (high signal intensity) on MRI T1 sequences. Emergent hormonal replacement and surgical decompression are the standard treatment.

Empty Sella

Empty sella is diagnosed radiographically by the herniation of the subarachnoid space into the sella, which displaces the pituitary gland against the floor of the inferior sella. Hypopituitarism is the main symptom and hormonal replacement is indicated. Although rare, these patients should be screened for intracranial hypertension and vision abnormalities.

THYROID DISEASE

Hypothyroidism

Hypothyroidism is defined as thyroid hormone deficiency. It can be overt (or clinical), with high TSH and low free T_4 levels, or subclinical with high TSH but normal free T_4 and usually a lack of symptoms. Thyroid hormone is important in early growth and development, and the neurologic consequences of hypothyroidism depend on the age at which the deficiency begins. Severe thyroid deficiency in utero or early in life results in delayed physical and mental development, known as *cretinism*. In adults, severe thyroid hormone deficiency can result in myxedema with or without coma.

Epidemiology

Hypothyroidism is a common disorder with an estimated prevalence of 0.3% to 3.7% in the United States and 0.2% to 5.3% in Europe. Congenital hypothyroidism due to maternal iodine deficiency or dysgenesis of the thyroid occurs in 1:3,000 to 1:4,000 births.

Pathobiology

The most common cause of primary hypothyroidism in iodine-sufficient countries is autoimmune destruction (Hashimoto disease), whereas iodine deficiency is the commonest cause in iodine-deficient regions. Hypothyroidism can also result after specific drug use; most commonly this is due to amiodarone, lithium, thalidomide, interferon-α, tyrosine kinase inhibitors, monoclonal antibodies, valproate, or drugs used for multidrug-resistant tuberculosis. Radioiodine treatment, neck radiation, and thyroidectomy can also result in hypothyroidism. Other, more rare causes of primary hypothyroidism include transient thyroiditis, infiltrative diseases, or genetic disorders.

Clinical Features

Congenital Hypothyroidism

In congenital hypothyroidism, subcutaneous tissue thickens, the cry becomes hoarse; the tongue enlarges; and the infant has widely spaced eyes, a potbelly, and an umbilical hernia. Neurologically, there is mental retardation with pyramidal and extrapyramidal signs in a mainly proximal distribution. Strabismus, deafness, and preservation of primitive reflexes are common. Precocious puberty may occur. Idiopathic intracranial hypertension has been reported in hypothyroid children receiving thyroid replacement therapy.

Neurologic Manifestations

The neurologic complications of hypothyroidism include headache, disorders of the cranial and peripheral nerves, sensorimotor abnormalities, and changes in cognition and level of consciousness. Mental status changes may be prominent, with decreased attentiveness, poor concentration, lethargy, and even dementia. Psychiatric symptoms—delirium, depression, or frank psychosis (myxedema madness)—may appear, depending on the severity and duration of thyroid deficiency. Cranial nerve abnormalities, other than visual and acoustic nerve problems, are unusual. Hearing loss, vertigo, and tinnitus may be present.

Neuromuscular Manifestations

Neuromuscular findings include slowing of voluntary movements and slow relaxation of tendon reflexes, particularly the ankle jerks. Electrically silent mounding of muscles on direct percussion is called *myoedema*. There may be exercise intolerance or myopathic weakness. Enlargement of muscles with pain and stiffness in adults produces the Hoffmann syndrome.

A mild, primarily sensory neuropathy is characterized mainly by paresthesias in the hands and feet. Entrapment neuropathy of the median nerve (carpal tunnel syndrome) is attributed to the accumulation of acid mucopolysaccharides in the nerve and surrounding tissues. Cerebellar ataxia (myxedema staggers) may occur in adults, manifesting as incoordination with a slow or stiff, unstable gait. Sleep apnea may result from myxedematous changes in the upper airway and hypertrophy of the tongue.

Myxedema

Myxedema is a rare but life-threatening condition with a mortality rate as high as 40%. It is characterized by lethargy, somnolence, or impairment of attention and concentration; weakness; slowness of speech; nonpitting edema of the subcutaneous tissues; coarse, pale skin; dry, brittle hair; thick lips; macroglossia; and increased sensitivity to cold. In more severe cases, myxedema coma may occur, accompanied by hypothermia, hypotension, and respiratory and metabolic disturbances. Early recognition and management is crucial.

Nonneurologic Manifestations

Hypothyroidism manifests with a variety of symptoms; cold intolerance, weight gain, constipation, change in voice, and dry skin are the most common. Cardiovascular signs include bradycardia, dyslipidemia, increased vascular resistance, decreased cardiac output and left ventricular function, pericardial effusion, and sometimes, hypertension. Mild anemia and bleeding may occur. Rarely, it is associated with worsening kidney function.

Diagnosis

The characteristic findings of primary hypothyroidism are low circulating free T_4 and T_3, elevated TSH, and low radioiodine uptake by the thyroid. Secondary or central hypothyroidism due to hypothalamic-pituitary disease will have reduced circulating thyroid hormones with low TSH. **Table 122.2** explains the relation of thyroid test functions with the etiologies of hypothyroidism.

Management

The treatment of hypothyroidism depends on the severity of the deficiency. Myxedema coma should be treated rapidly with intravenous administration of T_4. In other patients, gradually increasing doses of oral levothyroxine (to 1.5-1.8 μg/kg/d) are recommended.

TABLE 122.2 Thyroid Function Test Abnormalities

TSH	Free Thyroxine	Differential Diagnosis
↔	↑	Overtreatment with levothyroxine TSH-secreting pituitary adenoma Thyroid hormone resistance
↔	↓	Central hypothyroidism Sick euthyroid syndrome TSH deficiencies
↑	↑	Nonadherence to therapy TSH-secreting pituitary adenoma Thyroid hormone resistance
↑	↔	Subclinical hypothyroidism Adrenal insufficiency TSH or TRH resistance syndromes
↑	↓	Autoimmune hypothyroidism Iodine deficiency Postradioiodine or thyroidectomy Medication side effect Postradiation of the head or neck Thyroid infiltration Consumptive hypothyroidism
↓	↑	Graves disease Thyroiditis Overtreatment with thyroxine Ectopic hyperthyroidism (functional thyroid cancer metastasis) Toxic multinodular goiter Toxic solitary adenoma
↓	↔	Subclinical hyperthyroidism Sick euthyroid syndrome T_3 toxicosis
↓	↓	Sick euthyroid syndrome Central hypothyroidism

Abbreviations: ↔, normal; ↑, increase; ↓, decrease; T_3, triiodothyronine; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone.

Older patient should be started on lower doses (25-50 μg daily). Overly rapid replacement in adults can precipitate angina pectoris or heart failure. In secondary hypothyroidism, thyroid replacement should not be started without concomitant corticosteroid replacement so as not to precipitate cortisol insufficiency. Prophylactic treatment of cretinism is important in areas with high rates of goiter, where iodine should be given to all pregnant women.

Treatment of subclinical thyroid disease (ie, normal thyroid hormone levels with elevated or depressed TSH levels) is controversial. Pregnant women with treated subclinical hypothyroidism may experience lower rates of pregnancy loss. In the general population, subclinical hypothyroidism has been reported to be associated with deficits in working memory that were reversible with T_4 replacement.

Hyperthyroidism

Thyroid hormone excess from the thyroid gland, with normal or high thyroid radioactive iodine uptake, defines hyperthyroidism. Thyrotoxicosis without hyperthyroidism can result from thyroid hormone excess from extrathyroid gland sources or release of stored hormone and it is characterized by low radioactive iodine uptake.

Epidemiology

Overt hyperthyroidism's prevalence is about 0.5% in Unites States and 0.5% to 0.8% in Europe. It affects women more commonly than men. It is more frequent in elderly and white populations as well as in iodine-deficient regions.

Pathobiology

In iodine-sufficient countries, the most common cause of thyrotoxicosis with hyperthyroidism is Graves disease, with an annual incidence of 20 to 50 cases per 100,000 inhabitants. In iodine-deficient regions, toxic multinodular goiter and toxic adenoma represent 50% of the causes. Less frequently, hyperthyroidism can result from trophoblastic tumors because TSH receptors are stimulated by human chorionic gonadotropin. Thyrotoxicosis without hyperthyroidism is much less common and usually results from thyroiditis, ingestion of thyroid hormone, or rarely from ectopic thyroid hormone production.

Clinical Features

Hyperthyroidism typically presents with an increased metabolic rate, abnormal cardiovascular and autonomic functions, tremor, and nervousness. Hyperthyroidism may be subtle in older patients with apathy, myopathy, and cardiovascular disease as the most prominent symptoms. It is associated with atrial fibrillation and cardioembolic stroke. Mental disturbances range from mild irritability to psychosis.

Thyroid Storm

Thyroid "storm" or "crisis" is usually precipitated by infection, surgery, or trauma in individuals with unrecognized hyperthyroidism. The cardinal symptom is high fever (usually greater than 39°C) accompanied by cardiac symptoms and central nervous system dysfunction. Nausea, vomiting, and abdominal discomfort are common. Affected individuals are confused or agitated and may present with psychosis. If untreated, level of consciousness may deteriorate to coma and seizures may occur. Neurologic signs such as bulbar weakness and corticospinal tract dysfunction have been described.

Ocular Symptoms

Ocular symptoms are common in hyperthyroidism. These may be seen as infrequent blinking, lid lag, or weakness of convergence and are distinct from the infiltrative ophthalmopathy known as *Graves ophthalmopathy*. The relationship of the eye disorder to thyroid status is not entirely clear. Onset of symptoms is gradual; exophthalmos is often accompanied by diplopia secondary to paresis of one or more ocular muscles. Clinically, eyelid retraction (Dalrymple sign) is first evident in 75% of cases, and pain is the most common symptom. Both eyes may be involved simultaneously, or exophthalmos in one eye may precede the other by several months. Papilledema sometimes occurs, and ulcerations of the cornea may develop secondary to failure of the lid to protect the eye. Symptoms can progress rapidly over a few months and may lead to complete ophthalmoplegia.

Neuromuscular Manifestations

Thyrotoxic myopathy is characterized by painless weakness and wasting of proximal muscles of the arms and legs. Deep tendon reflexes are normal or hyperactive, and sensation is normal. The occurrence of hyperthyroidism and periodic paralysis is more common in people of Asian ancestry and is similar to hypokalemic periodic paralysis in terms of precipitants and treatment. There is an association between hyperthyroidism and myasthenia gravis; about 5% of patients with myasthenia gravis also have hyperthyroidism.

Diagnosis

A low TSH is the best test for diagnosis. Obtaining a free T_4 should follow this. If the free T_4 is not elevated, a free T_3 measurement may be elevated, indicative of T_3 toxicosis. The radioiodine uptake by the thyroid is the next test, which is most helpful in distinguishing the different causes of hyperthyroidism. Other tests are available if the use of radioisotope studies is contraindicated or not preferred, such as thyroid ultrasound with TSH-receptor antibodies measurement. Orbital imaging will be abnormal in thyroid ophthalmopathy. Table 122.2 shows the thyroid function test abnormalities associated with hyperthyroidism.

Management

β-Adrenergic blockade (eg, propranolol 10-40 mg four times a day) is appropriate for symptomatic treatment of tremor or myopathy. Methimazole (5-120 mg daily, depending on severity) and propylthiouracil (50-300 mg three to four times a day) are antithyroid medications that inhibit thyroid hormone synthesis. Agranulocytosis is a rare but major side effect of antithyroid drugs, usually within the first 90 days of treatment. If this is suspected and confirmed, antithyroid drugs should be stopped immediately. Ablation with radioactive iodine (^{131}I) or thyroidectomy is useful in treating various etiologies of hyperthyroidism that cannot be managed with medical therapies. Thyroid storm is a medical emergency with a mortality of around 20%. Immediate goals of treatment are to inhibit thyroid hormone synthesis and release, control cardiac symptoms, and support systemic circulation. High-dose propylthiouracil is theoretically preferred because of its earlier onset of action and its capacity to inhibit peripheral T_4 conversion to T_3. Treatment of thyroid ophthalmopathy is controversial and may include immune suppression with corticosteroids, radiotherapy, or surgical decompression of the orbit. Successful treatment of hyperthyroidism results in improvement of most symptoms. Patients will need to be followed at varying intervals depending on the type of treatment that is selected.

DIABETES MELLITUS

Epidemiology

In 2015, diabetes mellitus (DM) was ranked as the sixth leading cause of disability that affects an estimated 415 million people worldwide, with the majority (approximately 90%) suffering from type 2 DM.

Etiology

Type 1 DM is characterized by pancreatic β-cell destruction leading to complete insulin deficiency. In type 2 DM, there is a pancreatic β-cell dysfunction leading to partial insulin deficiency and insulin resistance in target organs.

Clinical Features

Neurologic Complications

The primary neurologic complication of DM is peripheral neuropathy, which is the most frequent type of neuropathy in Western countries. DM neuropathy affects up to 60% of individuals with diabetes. Its incidence increases with duration of DM and with poor glycemic control. Abnormalities reported in diabetic neuropathy include axonal degeneration of nerve fibers, primary demyelination resulting from Schwann cell dysfunction, secondary segmental demyelination related to impairment of the axonal control of myelination, onion bulb formation, and hypertrophy of the basal lamina. Endoneurial capillaries often show signs of diabetic microangiopathy with marked thickening of the basal lamina. Both metabolic and ischemic mechanisms may cause diabetic neuropathies. The neuropathies include mononeuropathies (peripheral and cranial nerves), polyneuropathy, autonomic neuropathy, radiculopathies, and entrapment neuropathy (median, ulnar, and peroneal). Mononeuropathies are attributed to inflammatory and/or vascular lesions of peripheral nerves, whereas metabolic abnormalities are likely to predominate in length-dependent diabetic polyneuropathy. Genetic factors might explain why some individuals develop a more severe polyneuropathy than others with a similar diabetic status. Common cranial neuropathies involve the oculomotor and abducens nerves. Pupillary sparing is common and is related to the pattern of presumed vascular damage within the oculomotor nerve. The prognosis for recovery from mononeuropathy or radiculopathy is good.

Diabetic retinopathy is the most common cause of acquired blindness in the Western world. Later stages can be associated with severe vision deficits. Early screening is recommended at 5 years after DM diagnosis in patients 15 years and older.

Macrovascular complications (cardiovascular and stroke) represent leading causes of disability and death in patients suffering from DM.

Diagnosis

Onset of symptoms is rapid, and pain is common in both mononeuropathies and radiculopathies caused by DM. In the more common distal symmetric polyneuropathies, there is typically a gradual onset of symptoms, the character of which depends on the type(s) of peripheral nerve fibers affected. Numbness and burning are common complaints. In symptomatic diabetic neuropathy, nerve conduction studies show slowing of nerve conduction velocity owing to demyelination and loss of large myelinated fibers, and a decrease in nerve action potentials owing to loss of axons. However, if the neuropathy primarily affects small myelinated or unmyelinated fibers, nerve conduction studies may be normal.

Diabetic neuropathy is diagnosed with funduscopic exam (direct ophthalmoscopy, indirect slit lamp funduscopy, digital fundus photography, or seven-field stereoscopic fundus photography) and is characterized by the presence of microaneurysms, exudates, retinal detachment, and vitreous hemorrhages.

Management

Optimal glycemic control diminishes the risk of developing a disabling peripheral neuropathy. Attention should be paid to protection of hyposensitive areas, notably the foot. Painful diabetic polyradiculopathies often respond to antineuralgia medications such as carbamazepine, gabapentin, and pregabalin. Spontaneous improvement in focal diabetic neuropathies typically occurs. Good glycemic control is the only way to minimize occurrence and/or progression of neuropathy. Glycemic control as well as hypertension and hyperlipidemia treatment with regular exercise and weight loss will decrease risk of macrovascular complications.

Similarly, in the case of diabetic retinopathy, tight glycemic, blood pressure, and lipid control is recommended. Laser therapy is reserved for sight-threatening situations.

FIGURE 122.4 Adrenal glands anatomy and hormones release. Abbreviation: ANS, autonomic nervous system. (© 1999-2016, Rice University. Download for free at http://cnx.org/contents/14fb4ad7-39a1-4eee-ab6e-3ef2482e3e22@8.24.)

ADRENAL DISEASE

The adrenal glands are retroperitoneal organs located above the kidneys. They consist of the adrenal cortex and adrenal medulla. The adrenal cortex is made up, from outer to inner layers, of the zona glomerulosa, which secretes aldosterone, the zona fasciculate, which secretes cortisol, and the zona reticularis, which secrets androgens and estrogens. The adrenal medulla synthesizes and secretes catecholamines (Fig. 122.4). Adrenal gland function is under hypothalamic-pituitary axis control, with the exception of the zona glomerulosa and aldosterone production, which is regulated by renin-angiotensin pathway.

Adrenal Insufficiency

Epidemiology

Primary adrenal insufficiency, also known as *Addison disease*, has an incidence of approximately 4.4 to 6 new cases per million in Europe. Age of diagnosis peaks between third and fifth decade, with women more frequently affected than men.

Pathobiology

Autoimmune adrenalitis is the most common cause of adrenal insufficiency, followed by infectious adrenalitis (due to tuberculosis, human immunodeficiency virus, syphilis, histoplasmosis, cryptococcosis, coccidioidomycosis, or trypanosomes). More rarely, adrenal insufficiency results from bilateral adrenal hemorrhage (due to meningococcal sepsis or primary antiphospholipid syndrome), bilateral adrenal metastasis, or bilateral adrenal infiltration (by lymphoma, amyloidosis, or hemochromatosis). Iatrogenic causes include after bilateral adrenalectomy or drug-induced (by etomidate, ketoconazole, fluconazole, phenobarbital, or phenytoin). Adrenal insufficiency may also result from abrupt discontinuation of chronic glucocorticoid treatment.

Adrenal insufficiency due to mutations in the *ABCD1* gene results in abnormal metabolism of long-chain fatty acids that characterizes X-linked adrenoleukodystrophy. Congenital adrenal hyperplasia, an autosomal recessive disorder, is the most common cause of adrenal insufficiency in children.

Clinical Features

Primary Adrenal Insufficiency

In primary adrenal insufficiency, typical systemic features result from lack of all adrenocortical hormones (aldosterone, cortisol, androgens) and include fatigue, anorexia, weight loss, hypotension, skin hyperpigmentation (only in primary chronic adrenal insufficiency), and hair loss. Headache is a common complaint. Mineralocorticoid deficiency produces hyponatremia with salt cravings. Cerebral symptoms include apathy, depression, confusion, and, rarely, psychosis. Muscle pain and cramping may occur, and hyperkalemic periodic paralysis has been described.

Adrenoleukodystrophy

In adrenoleukodystrophy, there is progressive central demyelination with impairment of cognition, vision, hearing, and motor function in children. A second phenotype with onset in the late 20s, called *adrenomyeloneuropathy*, involves spastic paraparesis and sphincter disturbances.

Adrenal Crisis

Adrenal crisis may manifest as acute deterioration in patients with known adrenal insufficiency due to precipitating factors such as infection, surgery, and psychological stress. Adrenal crisis may be the first manifestation in undiagnosed adrenal insufficiency. It is a medical emergency and primary symptoms consist of profound hypotension and shock with weakness, anorexia, fever, vomiting, abdominal pain, electrolyte abnormalities (hyperkalemia, hyponatremia), confusion, or even coma.

Diagnosis

Measurement of early morning serum cortisol (6:00-8:00) and plasma ACTH generally distinguishes patients with primary adrenal insufficiency from healthy individuals and those with secondary adrenal insufficiency. The standard short corticotropin test, in which serum cortisol is measured after intravenous ACTH, demonstrates the impairment of the adrenal cortex response to ACTH. In secondary adrenal insufficiency, there may be little difference in baseline hormone measurements compared to healthy individuals. The insulin tolerance test, a powerful activator of the hypothalamic-pituitary axis, remains the gold standard for assessment of secondary adrenal insufficiency. However, this test poses a significant burden on both the patient and the physician and tests such as the short corticotropin test, which capitalizes on the relative adrenal unresponsiveness to ACTH in secondary disease, are most often used. Because hypoadrenalism may cause neurologic symptoms in adrenoleukodystrophy or adrenomyeloneuropathy, this diagnosis should be considered in young men with adrenal insufficiency.

Management

Hydrocortisone 15 to 25 mg/d is given in two or three divided doses daily, with a larger dose administered in the morning to

mimic the pattern of physiologic cortisol secretion. Presurgical dose adjustment is required as well as an increase in daily dose for the first postoperative days. Mineralocorticoid replacement (fludrocortisone 50-200 μg/d) is required only for primary adrenal insufficiency and only if daily hydrocortisone dose is less than 50 mg daily. In adrenal crisis, treatment consists of hydrocortisone 100 mg (intravenous or intramuscular) followed by 100 to 300 mg/d (as boluses or infusion) until recovery. Patients suffering from adrenal insufficiency should be educated on how to use intramuscular hydrocortisone in case of stress or infectious disease and when to seek medical attention.

Hyperadrenalism

Cushing Syndrome

Excessive secretion of glucocorticoids from the adrenal glands produces *Cushing syndrome*, or primary hypercortisolism. Cushing disease, which is ACTH-dependent and related mainly to pituitary tumors (and less frequently to ectopic ACTH production, ie, small cell lung carcinoma) has already discussed previously in this chapter (under pituitary disorders). Neurologic impairment is a devastating result; over time, global cerebral atrophy and increased muscle protein degradation will occur.

Epidemiology

The incidence of primary Cushing syndrome is 0.7 to 2.4 per million inhabitants in Europe and 0.2 to 5 per million people per year worldwide.

Pathobiology

ACTH-independent hyperadrenalism is usually due to an adrenal carcinoma or unilateral or bilateral adrenal adenoma and more rarely due to ACTH-independent macronodular adrenal hyperplasia.

Clinical Features

The physical examination in Cushing syndrome may demonstrate hypertension, plethoric facies, hirsutism, centripetal obesity, a posterior neck fat pad (buffalo hump), purple abdominal striae, and bruising. DM, gonadal dysfunction, and osteoporosis are prominent features. Cognitive changes (impaired memory, visual-spatial processing, verbal learning, and language performance) with mood disorders (particularly major depression), myopathic weakness, and headache are the most common neurologic features. Myelopathy or radiculopathy may result from epidural lipomatosis.

Diagnosis

The diagnosis of Cushing syndrome is very challenging and despite the classical clinical manifestations, the presentation can be quite nonspecific. The initial step is distinguishing Cushing syndrome from individuals with Cushing-like states where hypercortisolism is a common feature. These include obesity, depression, or alcoholism. There is no test that has absolute diagnostic accuracy. First-line screening is a 24-hour urinary free cortisol and overnight dexamethasone suppression test or late-night salivary cortisol. After Cushing syndrome has been established, plasma ACTH is measured. If ACTH is suppressed, then adrenal-dependent Cushing is suspected. There are many potential pitfalls; thus, consultation with an experienced endocrinologist is essential. Adrenal tumors or tumors as a source of ectopic ACTH will require imaging for localization.

Management

Treatment depends on the etiology. In cases where there is an adrenal tumor secreting cortisol, surgical removal of the tumor is the first-line treatment. Medical therapy includes various drugs that interfere with synthesis and secretion of cortisol. Ketoconazole (200-400 mg twice a day to three times a day), an antifungal compound that inhibits steroidogenesis, is the most widely used medication in the United States for this purpose. Evidence suggests that resolution of hypercortisolism does not completely resolve symptoms. Reduced brain volume and cognitive behavioral symptoms may only be partially reversible. Cognitive problems and psychopathology may persist even after long-term serum cortisol normalization.

Hyperaldosteronism

Epidemiology

Hyperaldosteronism is the most common disorder of the adrenal zona glomerulosa and the most common form of secondary hypertension. Table 122.3 lists indications for hyperaldosteronism screening.

Pathobiology

Aldosterone, typically produced by an adrenal adenoma or bilateral adrenal hyperplasia, is inappropriately elevated. Adrenocortical adenocarcinoma and familial hyperaldosteronism are rare causes of hyperaldosteronism.

Clinical Features

The principal clinical feature is hypertension with hypokalemia. There appears to be a higher incidence of stroke in patients with hypertension from primary aldosteronism when compared to patients with essential hypertension. Hypokalemic alkalosis can lead to muscle weakness, paresthesias, tetany, or paralysis. Recurrent attacks of muscle weakness may simulate periodic paralysis. Paresthesias may occur as a result of alkalosis. Vertigo may be caused by abrupt fluid and electrolyte shifts. Idiopathic intracranial hypertension has been reported. Many patients may suffer from mood disorders.

Diagnosis

The Endocrine Society clinical practice guidelines recommend testing for a variety of types of individuals (see Table 122.3). The aldosterone-to-renin ratio is a widely used screening test, but many antihypertensive medications, oral contraceptives, or selective serotonin reuptake inhibitors can compromise sensitivity or specificity.

TABLE 122.3 Patients in Whom to Consider Hyperaldosteronism Screening

Uncontrolled BP >140/90 mm Hg resistant to three antihypertensive medications
Controlled BP<140/90 mm Hg on four or more antihypertensive medications
Hypertension with hypokalemia (spontaneous or induced by low-dose diuretic)
Hypertension with incidental finding of adrenal abnormality
Hypertension with first-degree relative diagnosed with primary hyperaldosteronism
Hypertension and family history of early-onset hypertension or stroke prior to age 40 years

Abbreviation: BP, blood pressure.

Management

Normalization of blood pressure should be the goal. Surgical removal of adrenal tissue or tumor is recommended when appropriate. Medical therapy with spironolactone can be particularly effective.

Pheochromocytoma

Epidemiology

Pheochromocytomas are rare neuroendocrine tumors with approximately 80% arising from the chromaffin cells of the adrenal medulla. The estimated incidence is 0.005% to 0.1% of the general population. They secrete catecholamines and cause an estimated 0.1% to 0.6% of cases of secondary hypertension.

Pathobiology

Pheochromocytomas may occur sporadically or as part of a hereditary syndrome. Pheochromocytoma may be seen with neurofibromatosis, von Hippel-Lindau disease, ataxia-telangiectasia, Sturge-Weber syndrome, or multiple endocrine neoplasia type 2. It is estimated that 25% are associated with known genetic mutations.

Clinical Features

Paroxysmal or sustained hypertension is the most typical clinical symptom. It can be associated with palpitations, episodic hyperhidrosis, headaches, and other nonspecific systemic symptoms, such as nausea, emesis, or diarrhea. Anxiety attacks are common. Death may result from cerebral hemorrhage, pulmonary edema, or cardiac failure complicating an acute attack or as a result of sustained hypertension.

Diagnosis

Diagnosis is made by demonstrating increased excretion of catecholamine metabolites in urine and localization of the tumor. Measurement of fractionated plasma or urine metanephrines (or both) is recommended. Food, caffeinated beverages, strenuous physical activity, or smoking are not permitted for at least 8 to 12 hours prior to testing. A greater than fourfold elevation of plasma metanephrines is highly suggestive of the presence of a tumor. Tumors may occur in sites other than the adrenal (eg, organs of Zuckerkandl). Computed tomography, MRI, or functional imaging techniques are helpful in tumor localization.

Management

Surgical removal of the pheochromocytoma is the treatment of choice. Preoperative blockade of catecholamines, most commonly with phenoxybenzamine (10-20 mg twice a day), for 2 weeks prior to surgery is required. Calcium channel blockers and selective α_1-adrenergic blockers are alternative preoperative treatments. Volume contraction is associated with chronic vasoconstriction; thus, volume expansion is recommended to reduce postoperative hypotension. Surgery is curative for local disease and surgical debulking for more advanced disease can facilitate radiotherapy or chemotherapy. Essential hypertension may persist in up to 20% of cases. Long-term follow-up with yearly measurement of catecholamines is recommended and is especially important for patients identified with genetic mutations associated with pheochromocytoma.

PARATHYROID DISEASE

The parathyroid glands secrete parathyroid hormone (PTH), which regulates calcium with direct effects on kidney and bone and indirect effects on the gastrointestinal tract. PTH secretion, in turn, is regulated by ionized calcium concentration in extracellular fluid. Thyrocalcitonin and vitamin D also play important roles in calcium metabolism. The principal effects of PTH on the nervous system are via calcium regulation. However, PTH receptors exist in the brain and an endogenous neuropeptide is their natural ligand. Their exact function is uncertain.

Hypoparathyroidism

Epidemiology

A prevalence of 37 per 100,000 person-years is estimated in United States with approximately total of 60,000 individuals having chronic hypoparathyroidism.

Pathobiology

Hypoparathyroidism is due to deficiency of PTH or lack of peripheral response to PTH (pseudohypoparathyroidism) due to abnormal PTH receptors, defects in receptor-linked enzyme activity, or circulating antagonists. Hypoparathyroidism occurs most commonly after thyroidectomy (approximately 1%-2% with experienced endocrine surgeons) or other neck surgery. Autoimmune hypoparathyroidism is the next most common cause. Hypoparathyroidism may also be a part of inherited disorders (eg, Kearns-Sayre syndrome or DiGeorge syndrome) or glandular destruction from infiltrative processes or radiation.

Clinical Features

Tetany is the most distinctive sign that may be manifested by carpopedal spasm. Latent tetany can be demonstrated by contracture of the facial muscles on tapping the facial nerve in front of the ear (Chvostek sign) or by evoking carpal spasm by inducing ischemia in the arm with an inflated blood pressure cuff (Trousseau sign). Patients may also present with paresthesias and cramps and if hypocalcemia is acute may manifest with seizures, bronchospasm, laryngospasm, or cardiac arrhythmias. Seizures are usually generalized, tend to be frequent, and respond poorly to anticonvulsant drugs.

Intracranial calcifications are common in hypoparathyroidism. The basal ganglia are the predominant site for calcium deposition, but other regions such as the cerebellum may be affected. The calcifications are usually not associated with symptoms, but cognitive impairment and a variety of hypokinetic (parkinsonism) and hyperkinetic (choreoathetosis, hemiballismus, torticollis) movement disorders have been reported. Increased intracranial pressure may complicate hypoparathyroidism. Sensorineural hearing loss and myopathy occur rarely.

Diagnosis

Hypocalcemia with an inappropriately low intact PTH level should lead to the suspicion of hypoparathyroidism. Hypomagnesemia can lower calcium and PTH. Hypocalcemia with low PTH essentially rules out other causes of hypocalcemia, such as vitamin D deficiency, malabsorption syndrome, or renal disease. In pseudohypoparathyroidism, PTH levels will be elevated, and

there are a variety of associated physical abnormalities. In most cases, there may be a relevant prior surgery or history of some destructive process (eg, radiotherapy) involving the parathyroid glands.

Management

There are no formal guidelines for management of chronic hypoparathyroidism. Treatment options include the use of calcium, vitamin D metabolites and analogues, and thiazide diuretics to enhance renal calcium reabsorption. Antiepileptic drugs that increase metabolism of vitamin D (eg, phenytoin) should be avoided so as not to potentially interfere with calcium absorption from the gut or calcium mobilization from bone. Neuromuscular symptoms and seizures resolve with restoration of calcium to normal levels. Movement disorders may also be reversible with appropriate treatment. However, the response of cognitive behavioral symptoms is variable.

Hyperparathyroidism

Epidemiology

Primary hyperparathyroidism is the most common cause of hypercalcemia. The most recent estimated incidence was approximately 22 cases per 100,000 per year. The prevalence of primary hyperparathyroidism in the United States is estimated at 0.86% with similar rates in Europe. It predominantly affects women with an approximate female-to-male ratio of 3 to 4:1, with highest peaks in the seventh decade.

Pathobiology

Single parathyroid adenoma is the most common cause of primary hyperparathyroidism, followed by multiglandular disease. Parathyroid cancer remains a very rare cause of primary hyperparathyroidism, despite an elevating incidence the last years. Genetic syndromes that are associated with primary hyperparathyroidism include multiple endocrine neoplasia type, 1, 2A, and 4; familial hypocalciuric hypercalcemia; and familial isolated primary hyperthyroidism. Drug-induced and secondary hyperparathyroidism should also be considered.

Clinical Features

The classic syndrome of hyperparathyroidism is hypercalcemia with a combination of renal lithiasis, osteitis, and peptic ulcer disease ("stones, bones, and abdominal groans"). However, with the ease of determining serum calcium concentration by routine automated blood chemistry tests, the diagnosis is frequently made with minimal clinical symptoms, and the classic triad is rarely seen today. Currently, it is estimated that 70% to 80% of individuals have no symptoms or signs of disease at the time of diagnosis.

Common symptoms include fatigue and subjective weakness. Mental status changes include impaired memory, personality changes, affective disorders, delirium, and psychosis. Elderly patients may be particularly susceptible to the effects of hypercalcemia. Parkinsonism and a syndrome resembling motor neuron disease, reversible with parathyroid surgery, have been described. "Brown tumors" seen in osteitis fibrosa cystica may cause myelopathy. Neuromuscular symptoms include proximal weakness, muscle pain and stiffness, and paresthesias. Tendon reflexes may be normal or hyperactive.

Diagnosis

The initial diagnosis typically occurs by finding hypercalcemia with hypophosphatemia on routine laboratory screening. A PTH level should be checked and will be elevated in hyperparathyroidism. Hypercalcemia with low or undetectable PTH levels may suggest cancer-associated hypercalcemia mediated by PTH-related protein or ectopic production of PTH. Electromyography and muscle biopsy can show nonspecific evidence of myopathic or neuropathic disease. Brown tumors show variable intensities on T2-weighted images with intense enhancement on T1-weighted contrast studies. Fluid-filled cysts may be detected.

Management

Parathyroidectomy normalizes serum calcium and is the treatment of choice for patients with symptomatic primary hyperparathyroidism. Localization of a parathyroid adenoma with a variety of imaging techniques is successful in 95% of cases. In patients with mild disease or who are not surgical candidates, bisphosphonates are an option. The calcimimetic drug cinacalcet often normalizes serum calcium concentration and modestly decreases PTH levels. Although the degree of hypercalcemia does not always correlate with clinical severity, most neurologic and neuromuscular manifestations typically improve with treatment. It remains controversial as to whether symptoms such as fatigue, subjective weakness, or neuropsychiatric symptoms remit with parathyroidectomy.

Hematologic Diseases and the Brain 123

Andreas H. Kramer

KEY POINTS

1. Anemia is a common concern among neurocritical care patients. Optimal transfusion thresholds may differ compared with other populations but require further evaluation in clinical trials.
2. Sickle cell disease is a major cause of stroke and cognitive decline in certain populations. Optimal management involves close monitoring for neurovascular disease and transfusion to maintain the proportion of hemoglobin S below 30%.
3. Leptomeningeal and subarachnoid spread is common with high-grade systemic lymphoma. Posttransplant lymphoproliferative disorder and primary central nervous system lymphoma may be responsible for parenchymal brain lesions in immunosuppressed patients.
4. Hyperviscosity with acute leukemia or plasma cell malignancies may require emergent plasmapheresis to avoid ischemic stroke.
5. The most common neurologic complication of thrombotic thrombocytopenic purpura is posterior reversible leukoencephalopathy syndrome, but ischemic stroke may also occur. Therapy consists of emergent plasma exchange.
6. Guidelines recommend transfusion to maintain platelet concentration above 50,000/μL and 100,000/μL in patients undergoing lumbar puncture and neurosurgical procedures, respectively. Routine platelet transfusion is not recommended for patient with intracerebral hemorrhage while receiving antiplatelet therapy.
7. Anticoagulants require emergent reversal in the setting of intracranial hemorrhage. Four factor prothrombin complex concentrate should be used for warfarin reversal, and specific reversal agents are now available for direct oral anticoagulants.

RED BLOOD CELL DISORDERS

Anemia is a common condition encountered in acute, severe neurologic illnesses such as stroke and traumatic brain injury (TBI). Maturation of hematopoietic stem cells into red blood cells (RBCs) in bone marrow is regulated by the glycoprotein hormone erythropoietin (EPO), which is released by peritubular cells in the kidneys in response to reductions in oxygen (O_2) delivery. Production of RBCs is also dependent on sufficient quantities of bone marrow substrate, including iron, folate, and vitamin B_{12}. The RBCs normally have a life span of 100 to 120 days before being removed by the spleen.

Anemia

Anemia is defined as a hemoglobin (HB) concentration of less than 12 g/dL in women and 13 g/dL in men. There are numerous possible etiologies for anemia, which are presented in Figure 123.1. Measurement of the reticulocyte count helps determine whether the bone marrow is responding "appropriately" to anemia—if so, it implies that the cause is hemorrhage or hemolysis; if not, there is a problem with RBC production. The RBC indices, especially the mean cell volume (MCV), provide further information concerning the differential diagnosis. Microcytosis (MCV <80 fL) implies that there is a cytoplasmic problem with the production of HB and the maturation of RBCs. Specific causes of microcytic anemia include iron deficiency and various hemoglobinopathies. Macrocytosis (MCV >100 fL) implies that there is a nuclear defect in developing RBCs, which may be due to vitamin B_{12} and folate deficiency or drug toxicity. Normocytic anemia suggests that there is a pathologic bone marrow process or that there is reduced stimulation for RBC production. This section focuses on the neurologic implications of anemia and on sickle cell disease (SCD), which is a major cause of stroke in children and young adults.

Anemia and Transfusion in Hospitalized and Critically Ill Neurologic Patients

Anemia is one of the most common medical complications to be encountered among hospitalized patients, especially in the intensive care unit. The development of an HB concentration less than 10 g/dL has been reported in about 40% to 50% of neurocritical care patients with TBI or subarachnoid hemorrhage (SAH). The etiology of anemia in hospitalized patients is multifactorial. The RBC production is impaired during systemic inflammation, as cytokines blunt the production of EPO and prevent progenitor cells from incorporating iron. The RBC loss is accelerated by the need for frequent phlebotomy, reduced RBC survival, and (in some cases) hemorrhage. Hemodilution produced by administration of large volumes of intravenous fluids and blood loss from phlebotomy may also contribute.

Optimal care of patients with acute brain injury and various forms of stroke involves the protection of salvageable brain tissue and prevention of secondary injury. Reduced O_2 delivery to ischemic penumbra may cause increasing neurologic damage. The amount of O_2 reaching tissues is the product of local blood flow and arterial O_2 content, which is determined by the HB concentration and degree to which it is saturated with O_2.

FIGURE 123.1 Approach to determining the etiology of anemia. Abbreviations: HB, hemoglobin; LDH, lactate dehydrogenase; MCV, mean cell volume; RBC, red blood cell.

Anemia is initially well tolerated by most patients for several reasons: Systemic O_2 delivery exceeds O_2 consumption by a large amount, tissues have the capacity to increase O_2 extraction, and sympathetic stimulation increases cardiac output. In the brain, the normal response to anemia is cerebral vasodilation, with a resulting increment in cerebral blood flow (CBF). Experiments in healthy volunteers demonstrate that neurocognitive impairment begins at an HB concentration below approximately 7 g/dL. It is likely that the HB threshold for neurologic deterioration is generally higher in brain-injured patients, in whom autoregulatory mechanisms may be impaired. It also seems unlikely that there is a single transfusion threshold that is optimal for all brain-injured patients.

The development of anemia is associated with worsened outcomes in patients with TBI, SAH, and intracerebral hemorrhage (ICH). Studies using invasive multimodal neurologic monitoring have found that anemia is associated with lower brain tissue O_2 tension and high cerebral lactate concentrations. Patients with SAH, in particular, are vulnerable to delayed cerebral ischemia. Administration of RBC transfusions improves O_2 delivery to the brain and increases physiologic "reserve" in regions of the brain with a high O_2 extraction fraction.

Historically, clinicians would give RBC transfusions to maintain HB concentrations greater than 9 to 10 g/dL in brain-injured patients. However, allogeneic RBC transfusions have potential adverse effects, including transfusion-related acute lung injury and immunosuppression with an increased risk of nosocomial infections. Randomized trials in general critical care patients have found no advantage, and possible harm, when RBC transfusions are used to routinely maintain HB concentrations above 10 g/dL compared with a transfusion threshold of 7 g/dL LEVEL 1.[1,2] However, there were few brain-injured patients in these studies, and HB concentrations of 7 to 9 g/dL may be too low in some brain-injured patients. There is substantial variability of practice, which will continue until definitive clinical trials are performed specifically in brain-injured patients. One moderate-sized randomized controlled trial of patients with severe TBI found that patients transfused at a threshold of 10 g/dL had higher brain tissue O_2 tension but did not have better outcomes compared with those transfused at a threshold of 7 g/dL.

Sickle Cell Disease

SCD is a group of genetic disorders characterized by the presence of "sickle hemoglobin" (HBS) caused by a mutation in the β-globin gene, whereby the sixth amino acid changes from glutamic acid to valine. The most common and severe form is sickle cell anemia, which occurs in patients homozygous for the HBS allele. There are other SCD variants where HBS is inherited from one parent and another abnormal HB from the other. Stroke is the most common neurologic complication of SCD.

Epidemiology

The global burden of SCD is increasing, especially in Africa and India. About 8% of African Americans are heterozygous for HBS and 1 in 600 are homozygous. Another 2% to 3% carry the HBC allele, which is attributable to a glutamic acid to lysine substitution. The incidence of stroke in children with SCD is increased about 300- to 400-fold, such that the chance of having a stroke by 20, 30, and 45 years of age is estimated to be about 11%, 15%, and 24%, respectively. Intracranial hemorrhage is less common but increases in incidence between 20 and 30 years of age. Stroke is a major cause of premature death and disability in patients with SCD. Untreated, stroke may recur in as many as two-thirds of patients within 2 years. By far, the strongest risk factor for stroke is a previous stroke or transient ischemic attack (TIA). Other risk factors include the degree to which HB is reduced, hypertension, frequent episodes of acute chest pain syndrome, leukocytosis, and lower pulse oximetry values.

Even in patients who have not developed overt stroke, magnetic resonance imaging (MRI) studies demonstrate that silent cerebral infarcts are common, occurring in more than a third of patients. Previous infarcts are seen especially in watershed regions and are associated with cognitive impairment and a higher subsequent risk of overt stroke. Areas of restricted diffusion,

suggestive of recent cerebral ischemia, can be detected even when patients are asymptomatic, suggesting that patients are at constant risk. Identified risk factors for silent cerebral infarcts include lower baseline HB concentration, higher systolic blood pressure, and male sex.

Pathobiology

O_2 is normally transported by adult hemoglobin (HBA) consisting of two α and β polypeptide chains that encircle a heme moiety. Unlike HBA, HBS has a tendency to polymerize when it is deoxygenated, which in turn disrupts the normal architecture and flexibility of RBCs, causing them to take on sickle-shaped morphology. Sickling of RBCs interferes with their transit through capillaries and venules, causes them to adhere to endothelium, and increases blood viscosity, all of which may produce microvascular occlusion and tissue ischemia. Increased hemolysis occurs in the spleen. Most of the clinical manifestations of sickle cell anemia are attributable either to vaso-occlusion or hemolysis.

Multiple other factors are implicated in causing cerebral ischemia. Adherence of sickled RBCs to vascular endothelium induces a cascade of events that produce leukocyte recruitment, inflammation, intimal hyperplasia, fibrosis, and thrombosis. Intravascular hemolysis and release of free HB scavenges nitric oxide, the production of which may also be impaired by endothelial damage, thereby interfering with maintenance of normal vascular tone. These factors contribute to impaired CBF autoregulation, making the brain vulnerable both to hyperemia and ischemia.

Imaging studies with digital subtraction or magnetic resonance (MR) angiography demonstrate that many patients have various forms of vasculopathy. By far, the most common cerebrovascular abnormality is stenosis of proximal intracranial vessels, especially in the anterior circulation, which may be accompanied by relative hypoperfusion if perfusion imaging is performed. Involvement of extracranial vessels is less common but does occur and may lead to cervical artery dissection and/or embolic strokes. Over time, with persistent severe intracranial stenosis, there may be development of collateral vessels resembling those of moyamoya disease. The presence of such collaterals is a marker of a greater degree of vasculopathy and has been identified as a major risk factor for future stroke. These friable vessels are also vulnerable to bleeding. Intracranial aneurysms may develop in unusual locations with a possible predilection for the posterior circulation.

Clinical Manifestations

SCD patients with cerebrovascular disease present most often with TIA or ischemic stroke. Among those with hemorrhage, SAH is more common than ICH or intraventricular hemorrhage. Repeated silent infarcts cause progressive neurologic deterioration and cognitive impairment. Neuroimaging reveals that patients with SCD have a greater degree of thinning of the frontal lobe cortex as well as reduced basal ganglia and thalamus volumes.

SCD may rarely cause complications in the spinal cord and peripheral nervous system. There have been numerous case reports of spinal cord infarction, most often involving the cervical cord and inducing quadriparesis. Ischemic injury of peripheral nerves presents as mononeuritis multiplex. Functional asplenia is a well-recognized complication of SCD. The resulting immunosuppression predisposes to bacterial infections, including meningitis, with the risk being high enough to justify prophylactic penicillin usage until at least the age of 5 years. Fever should therefore be considered a medical emergency.

Diagnosis

The diagnosis of SCD is confirmed by HB electrophoresis. Quantification of the percentage of HBS, determined by high-performance light chromatography, is important for therapeutic decision making. Ischemic strokes are rare in the absence of detectable abnormalities in the cerebral vasculature. When vasculopathy is present, the risk of stroke can be significantly ameliorated with appropriate therapy. Thus, screening of patients for cerebrovascular disease is important. Cerebral vasculature is best imaged with digital subtraction angiography, but noninvasive imaging is preferred. Both computed tomography (CT) and MR angiography can be used, although published experience is larger with the latter. Previous concerns that intravenous contrast could precipitate sickling crisis have likely been exaggerated.

In experienced hands, transcranial Doppler (TCD) ultrasonography correlates well with angiography. Increased TCD velocities in the anterior circulation are highly predictive of the risk of subsequent stroke LEVEL 3.[3] In one prospective single-center study, the sensitivity and specificity for subsequent overt stroke exceeded 85% when TCD velocity exceeded 170 cm/s. In children, when TCD velocities in either middle cerebral or intracranial internal carotid artery consistently exceed 200 cm/s, a randomized controlled trial demonstrated that a prevention strategy using RBC transfusions decreased the risk of stroke over the ensuing 2 years from 16% to 2% LEVEL 3.[4] The risk of stroke is even higher if there are elevated velocities in more than one vessel. Annual screening with TCD is recommended for children with SCD beginning at 2 years of age. Implementation of screening has been temporally associated with a reduction in the incidence of stroke in some jurisdictions. Most studies assessing the use of TCD in SCD have been in children. The TCD velocities that are associated with vascular stenosis seem to be somewhat lower in adults, and it is unclear whether TCD is as predictive of subsequent stroke risk.

Apart from imaging of the intra- and extracranial cerebral vasculature, patients with SCD who develop ischemic strokes should undergo a similar diagnostic evaluation to that of other patients, including an echocardiogram, lipid panel, and assessment for diabetes mellitus. In patients with SAH or ICH, if CT or MR angiography does not demonstrate a cause, a digital subtraction angiography should be considered to ensure that a small aneurysm or vascular abnormality is not being missed.

Management

SCD is a multisystem condition, and the management of neurologic complications occurs in the context of other concomitant treatment considerations. In the management of cerebrovascular complications, therapeutic goals are the primary and secondary prevention of strokes, including those that are silent and may contribute to cognitive decline as well as minimization of brain injury when strokes do occur. In a randomized controlled trial, antiplatelet therapy with prasugrel was ineffective in the primary prevention of TIA and stroke LEVEL 3.[5]

Transfusion Strategies and Stroke Prevention

The Stroke Prevention Trial in Sickle Cell Anemia (STOP) demonstrated that using RBC transfusions to keep the fraction of HBS less than 30% (Table 123.1) significantly reduces the risk

TABLE 123.1 Indications for Chronic Transfusion Program for the Prevention of Stroke in Patients With Sickle Cell Disease

Primary prevention (screen annually with TCDs of MCA and distal ICA between 2 and 16 y)
• If >220 cm/s, initiate transfusion program. • If 200-220 cm/s, repeat TCDs in 1-2 wk and initiate transfusion program if confirmed >200 cm/s. • If 170-200 cm/s, repeat TCDs in 3-6 mo; consider MRI scan to assess for SCI. • If <170 cm/s, repeat TCDs annually; consider MRI scan to assess for SCI.
Secondary prevention (if patient has had symptomatic stroke)
MRI evidence of silent cerebral infarction (Note: Optimal frequency of MRI screening has not yet been defined.)

Abbreviations: ICA, internal carotid artery; MCA, middle cerebral artery; MRI, magnetic resonance imaging; SCI, silent cerebral infarction; TCD, transcranial Doppler.

of stroke LEVEL 1.[4] Apart from diluting HBS with the addition of HBA, transfusions also temporarily reduce EPO production, thereby reducing the production of new HBS. The O_2 binds more efficiently to HBA than HBS, such that the O_2 saturation is temporarily increased. Although the STOP trial was a primary prevention study, chronic transfusion therapy has also been widely adopted as a secondary prevention strategy. The target HB concentration is generally greater than 9 g/dL. An HB concentration of >12.5 g/dL should likely be avoided because increasing viscosity may interfere with tissue O_2 delivery. Simple transfusions can be performed when patients are very anemic. Exchange transfusions refer to the transfusion of RBCs together with the removal of the patient's blood, which is more effective at reducing the concentration of HBS and at lowering stroke incidence.

The need for regular transfusions also has risks, most notably the development of iron overload. Over time, excess iron overwhelms the capacity of reticuloendothelial system to sequester it, and iron begins to accumulate in organs, especially the liver. The consequence of unchecked iron accumulation is hepatic fibrosis and eventually cirrhosis. Rather than performing repeated biopsies, liver iron burden can be accurately monitored noninvasively with annual quantitative MRI scans. Increasing liver iron concentration or serum ferritin (>1,500 μg/L) is an indication to initiate treatment with an iron chelator, most often deferasirox, which has similar efficacy to deferoxamine but is orally available. In an attempt to avoid long-term dependence on blood transfusions, the STOP 2 trial assessed the safety of discontinuing prophylactic transfusions in children whose TCD results had normalized over time. Unfortunately, cessation of transfusions was associated with a clear increment in TCD velocities over time as well as an increased risk of recurrent stroke LEVEL 1.[6]

Post hoc analyses of the STOP trials indicated that new silent infarcts were reduced by the use of transfusions and that discontinuation of transfusions led to an increment in the occurrence of new infarcts. However, patients treated with chronic transfusion still commonly develop progressive cerebral vasculopathy. Increased TCD velocities are not necessarily predictive of the development of silent infarcts. The MR angiography may be more predictive, but the relationship between burden of vasculopathy and risk of infarction is imperfect. Until recently, it was unclear whether performing serial MRI scans to document silent infarcts is helpful and should modify the therapeutic approach. However, the Silent Cerebral Infarct trial has demonstrated that regular transfusions to maintain HBS less than 30% and HB greater than 9 g/dL reduces the incidence of subsequent overt or silent infarcts LEVEL 1.[7] Patients should be periodically screened for silent infarcts (the optimal interval has not been defined) and enrolled in a transfusion program if they are present.

Management of Acute Stroke

There have been no randomized trials of thrombolysis or endovascular thrombectomy specifically in the treatment of pediatric stroke. The pathophysiology of acute stroke in the setting of SCD may not be the same as in other situations. Nevertheless, although the risk of iatrogenic hemorrhage may be higher, the presence of SCD is not necessarily a contraindication for the use of thrombolytics, especially if the stroke mechanism involves acute thrombotic or embolic vascular occlusion. The CT angiography, performed immediately after an initial noncontrast CT scan, can help clarify the mechanism while concomitantly identifying vascular abnormalities that may constitute a relative contraindication. Urgent transfusion to lower the HBS concentration and raise the total HB concentration to about 10 g/dL is appropriate to maximize O_2 delivery to the affected penumbra. Adequate hydration and avoidance of hypotension, hyperglycemia, and fever are other standard measures. Antiplatelet therapy is indicated in adults sustaining acute strokes in other settings, but there is no data specifically in patients with SCD. The very high risk of recurrent stroke with SCD justifies the use of chronic transfusion for secondary prevention.

Hydroxyurea as an Alternative to Chronic Transfusion

Fetal hemoglobin (HBF) consists of two gamma, rather than beta, globulins. For this reason, an increased concentration of HBF in the circulation prevents the sickling of RBCs. Hydroxyurea is thought to exert its beneficial effects in SCD by increasing the formation of HBF. A large randomized trial found hydroxyurea to reduce painful vaso-occlusive crises. Long-term follow-up demonstrated a possible mortality benefit LEVEL 1.[8] Hydroxyurea is currently recommended in patients older than 24 months with frequent pain crises, acute chest syndrome, or severe symptomatic anemia. There has been interest in using hydroxyurea as an alternative to chronic transfusion in the prevention of cerebrovascular disease. Early data suggested that hydroxyurea might be efficacious. However, among children with previous stroke, the Stroke with Transfusions Changing to Hydroxyurea trial demonstrated that discontinuing regular transfusions and instead treating patients with hydroxyurea resulted in an increased recurrent stroke risk LEVEL 1.[9] In contrast, the TCD with Transfusions Changing to Hydroxyurea trial found that among children with elevated TCD velocities, but no previous stroke, transitioning to hydroxyurea after at least 1 year of transfusions did not result in higher TCD velocities or an increased risk of stroke LEVEL 1.[10]

Intracranial Hemorrhage and Moyamoya Syndrome

Supportive care of SAH and ICH is not different compared with patients who do not have SCD. Immediate priorities with SAH are cardiopulmonary stabilization and treatment of hydrocephalus. Cerebral angiography (invasive or noninvasive) is required to identify the source of bleeding. Most aneurysms with SCD appear to be saccular and are amenable to clip ligation or coil embolization. Some aneurysms are fusiform and can be treated with endovascular stenting. Nimodipine should be used for prevention of delayed cerebral ischemia.

Moyamoya syndrome, characterized by progressive intracranial large-vessel occlusion, is a recognized and relatively common complication of sickle cell vasculopathy that is associated with an increased risk of stroke and cognitive decline (see also Chapter 44). There are no controlled studies assessing the optimal management of moyamoya syndrome specifically in the context of SCD. In the setting of an acute ischemic stroke, physiologic targets (blood pressure, P_{CO_2} and O_2, core body temperature) should be directed at optimizing cerebral perfusion and protecting vulnerable ischemic penumbra. Surgical revascularization is generally preferred for secondary prevention. Small case series have suggested a reduced risk of ischemic stroke with surgery. In adults, direct revascularization with a superficial temporal artery to middle cerebral artery bypass procedure may be possible. In children or in adults without a suitable target vessel, indirect revascularization procedures (eg, pial synangiosis) are more often performed.

Polycythemia

Polycythemia is present when the HB concentration is greater than 16.5 g/dL in women and 18.5 g/dL in men (or the hematocrit is >48% and 52%, respectively). True polycythemia should not be attributable solely to a reduction in plasma volume (hemoconcentration). "Primary" polycythemia refers to increased production of RBCs without increased release of EPO and occurs as a result of congenital or acquired mutations in RBC progenitors. "Secondary" polycythemia is an appropriate response to increased EPO production (Fig. 123.2). Management of secondary polycythemia should be directed at the underlying cause.

Polycythemia Vera

Polycythemia vera (PV) is of interest to neurologists primarily as a cause of stroke. The median age of diagnosis is about 60 years, but PV can occur across all age categories. In almost all cases, PV is associated with a mutation involving JAK2, a gene located on chromosome 9 that codes for the production of tyrosine kinase, a family of proteins that participate in the regulation of hematopoietic cell proliferation. The same mutation is present in about 50% of patients with essential thrombocythemia (ET) and primary myelofibrosis.

Pathobiology

A PV is a myeloproliferative neoplasm characterized by the clonal proliferation of RBC progenitors resulting in an elevated RBC mass. A small proportion of patients with PV will develop leukemic transformation, usually after many years. A major concern with PV and other myeloproliferative disorders is a predisposition to thrombosis. It is thought that persistently elevated viscosity produces high shear stress in blood vessels, which in turn is complicated by endothelial dysfunction, as well as platelet and leukocyte activation. Increased levels of thromboxane and other markers of platelet activation can be detected in the blood of patients with PV. High viscosity may reduce CBF to a degree that overall O_2 delivery is impaired despite the higher O_2-carrying capacity produced by a higher HB concentration. However, other factors must be at play because there is no clear evidence that secondary polycythemia increases the risk of thrombosis.

Clinical Manifestations

A PV is sometimes detected incidentally on routine blood work. However, a sizable proportion of patients have already had thrombotic events by the time they come to medical attention. Arterial thrombosis is more common than venous thrombosis. Patients may also present with transient visual disturbances, headaches, and dizziness attributable to hyperviscosity and sluggish blood flow. Other common complaints include pruritus that is exacerbated by contact with water and erythromelalgia (burning sensation in extremities with erythema or pallor). Physical examination commonly demonstrates hepato- and splenomegaly as well as facial plethora. Apart from an elevated HB concentration, other laboratory findings include thrombocytosis, leukocytosis, high lactate dehydrogenase (LDH), and low EPO levels. Major diagnostic criteria for PV include an elevated HB concentration and the presence of the JAK2 mutation. Minor criteria include characteristic findings on a bone marrow aspirate or biopsy and reduced serum EPO.

Management

The goal of treatment is to reduce symptoms and the risk of thrombosis while also minimizing long-term complications, especially leukemia. In a multicenter randomized trial involving patients with JAK2-positive PV, treatment with phlebotomy or hydroxyurea to achieve a hematocrit of less than 45% was associated with a significant reduction in thrombotic events. This target hematocrit should therefore be maintained with phlebotomy in essentially all patients LEVEL 2.[11] For patients at especially high risk for thrombosis (those older than the age of 60 y or having had previous thrombotic events), treatment with

FIGURE 123.2 Approach to determining the etiology of polycythemia. Abbreviations: CO, carbon monoxide; EPO, erythropoietin; HB, hemoglobin; O_2, oxygen.

hydroxyurea is recommended, as it appears to further reduce the risk of thrombosis with a smaller increase in the risk of leukemia over time compared with other myelosuppressive drugs. The addition of low-dose aspirin (80 mg/d) can further reduce thrombotic risk LEVEL 2.[12] Use of the JAK1 and JAK2 inhibitor ruxolitinib has been demonstrated in a randomized controlled trial to reduce the hematocrit, improve splenomegaly, and improve symptoms associated with PV. There was also a possible trend toward fewer thromboembolic events, although the trial was not powered to detect a difference LEVEL 3.[13]

WHITE BLOOD CELL DISORDERS

Malignancies of Lymphoid Cells

Lymphoma, Lymphoblastic Leukemia, and Posttransplant Lymphoproliferative Disorders

Lymphoid malignancies present primarily as mass lesions, which are referred to as *lymphoma*, or with cancer cells in the blood, referred to as *leukemia*. They are most often categorized using the World Health Organization classification system. Lymphoma is divided broadly as Hodgkin and non-Hodgkin (NHL). The NHL encompasses a heterogeneous group of malignancies, arising from B lymphocytes in about 85% to 90% of cases, and T lymphocytes in about 10% to 15% of cases. B- and T-cell lymphomas are further subdivided based on whether the malignancy involves proliferation of immature precursor cells or mature cells. Neurologic involvement is rare with Hodgkin lymphoma. However, with NHL and acute lymphoblastic leukemia (ALL), neurologic complications may occur because of direct infiltration of cancer cells into the central nervous system (CNS) (Table 123.2).

Primary CNS lymphoma (PCNSL) is an extranodal variant of NHL that may involve the brain, leptomeninges, eyes, or spinal cord. It usually develops in the setting of immunosuppression. Posttransplant lymphoproliferative disorders (PTLDs) are a group of conditions involving proliferation of lymphoid or plasmacytic cells in the context of immunosuppression; involved cells usually harbor Epstein-Barr virus (EBV). The spectrum of conditions ranges from an infectious mononucleosis-like illness to malignancy that may or may not meet criteria for lymphoma.

TABLE 123.2 Classification of Most Common Subtypes of Non-Hodgkin Lymphoma and Approximate Prevalence of Central Nervous System (CNS) Involvement

Type of Lymphoma	Prevalence of CNS Involvement
Indolent lymphomas	**1%-3%**
• Follicular lymphoma (grades I and II) • Marginal zone B-cell lymphoma • Small lymphocytic lymphoma/ B-cell CLL	
Aggressive lymphomas	**3%-5%**
• Diffuse large B-cell lymphoma • Follicular lymphoma (grade III) • Mantle cell lymphoma • Peripheral T-cell lymphoma • Anaplastic large cell lymphoma	Note: Prevalence higher with certain risk factors (eg, involvement of testes, orbits, nasopharynx, breasts, multiple extranodal sites, high serum LDH).
Highly Aggressive Lymphomas	**25%-50%**
• Burkitt lymphoma • Precursor T and B lymphoblastic lymphoma • Adult T-cell lymphoma	

Abbreviations: CLL, chronic lymphocytic leukemia; LDH, lactate dehydrogenase.

Epidemiology

The distribution of NHL subtypes varies by region. In Western countries, diffuse large B-cell lymphoma and follicular lymphoma account for more than 50% of cases. The CNS involvement is most common with very high–grade lymphomas, especially Burkitt lymphoma and acute lymphoblastic lymphoma, where it may be present at the time of diagnosis in as many as a third. However, CNS involvement also occurs with intermediate- and high-grade lymphoma subtypes, including diffuse B-cell lymphoma, especially when there is lymphoma spread to testes, orbits, or the nasopharynx and when there is a high serum LDH concentration. Most cases with neurologic involvement manifest as disease relapses during or after initial treatment, even when there has been a favorable systemic response to treatment, suggesting that subclinical disease was present at the time of diagnosis. The proportion of patients developing CNS relapses may have decreased over time with the addition of rituximab to standard CHOP therapy.

More than half of cases of ALL occur in children, with a peak incidence between the ages of 2 and 5 years. The CNS infiltration is detected at diagnosis in about 5% to 10% of patients. This is likely to be an underestimate, given that identification of CNS involvement may be challenging and is not routinely pursued. Before routine use of prophylactic therapy, CNS relapses occurred in as many as 80% of cases. The CNS involvement was sometimes identified at autopsy in patients previously thought to have had more limited disease. Risk factors for CNS leukemia include younger age, high white blood cell (WBC) count, positive Philadelphia chromosome, and T-cell ALL.

PCNSL accounts for about 4% of brain tumors and may be a complication of advanced human immunodeficiency virus infection or occur following organ transplantation, although sporadic cases also occur. The EBV may be pathogenic in some cases of PCNSL as well as when more widespread PTLD involves the CNS. Following primary infection, EBV remains quiescent in some B lymphocytes. With suppression of T cell immunity, there may be polyclonal or monoclonal proliferation of these cells. The PTLD accounts for about 20% of malignancies following solid organ transplantation and occurs more frequently with more intensive immunosuppressive regimens. About a quarter of patients with PTLD have CNS involvement.

Clinical Manifestations

When diffuse lymphoma involves the CNS, the location is most often the leptomeninges and subarachnoid space. Brain parenchyma involvement is less common. This differs with PCNSL, where lesions typically arise in a periventricular distribution, with corpus callosum, basal ganglia, and thalamus involvement, although cortical lesions also occur.

The predilection of certain tumor subtypes for CNS penetration may relate to expression of various surface adhesion molecules. The most frequent manifestations of leptomeningeal involvement include headache, neck pain, and various cranial neuropathies. If there is spread to the lumbar cistern, patients

may develop low back pain and radiculopathies. The degree of subarachnoid involvement may be severe enough to interfere with cerebrospinal fluid (CSF) flow and cause hydrocephalus. With brain parenchymal involvement, there is a risk of developing seizures and focal deficits. Intramedullary spinal cord involvement is rare. In contrast, NHL and multiple myeloma (MM) are among the most common malignancies to cause extrinsic spinal cord compression (see Chapter 17).

Diagnosis

Gadolinium-enhanced MRI can identify leptomeningeal or brain parenchymal spread. There may be enhancement and thickening of the meninges or individual cranial nerves or nerve roots. There are no characteristic MRI features that definitively identify cerebral mass lesions as lymphoma rather than other tumors, although necrosis or ring enhancement would be unusual. In cases of PCNSL, stereotactic biopsy is usually required to make the diagnosis.

CSF findings include lymphocytic pleocytosis, elevated protein, normal or reduced glucose, and high opening pressure, although most patients do not have all of these. The CSF cytology and flow cytometry should both be performed, as they provide complementary information. Sampling CSF more than once may reduce false-negative rate. The CNS leukemia is defined by the presence of leukemic blasts in CSF. Blasts may occur regardless of whether or not the CSF WBC count is increased. The presence of CSF blasts predicts a worse prognosis.

CNS PTLD has different neuroimaging findings than PCNSL: It is usually multifocal, involves the cortex more than periventricular regions, has irregular margins with heterogenous enhancement, and commonly produces restricted diffusion. A diagnosis of CNS PTLD is supported by high titers of EBV in blood and CSF. However, confirmation still requires either a tissue diagnosis or identification of malignant lymphocytes in CSF.

Management

Lymphoma

When NHL is complicated by secondary CNS involvement, the usual treatment approach must be modified. Options include intensification of the chemotherapeutic regimen, with inclusion of higher doses of drugs that cross the blood-brain barrier or delivering chemotherapy directly into the CNS using either an Ommaya reservoir or repeated lumbar puncture. It is unclear which of these approaches is preferred, as they have not been compared in large clinical trials.

When systemic chemotherapy is used, the regimen usually includes high-dose methotrexate. Combining high-dose chemotherapy with autologous stem cell transplantation appears to be a promising approach. Intrathecal therapy consists of methotrexate in combination with cytarabine. Preliminary data suggest that cytarabine is more efficacious when administered as a slow-release liposomal formulation, which has the additional advantage of requiring less frequent administration. Systemic corticosteroids are effective in some patients at temporarily ameliorating neurologic symptoms and providing analgesia. Radiation therapy may be helpful in selected cases where there are radiographically visible lesions that are causing symptoms.

Because the prognosis of NHL is much worse with relapses that involve the CNS, some experts favor administration of prophylactic CNS therapy as a component of the initial chemotherapeutic regimen in patients deemed to be at high risk. The risk of CNS involvement is sufficiently high with Burkitt lymphoma and lymphoblastic lymphoma to justify CNS prophylaxis. This may also be appropriate other forms of NHL if risk factors for CNS involvement are present.

Surgical resection has a limited role, even with PCNSL, because brain involvements tend to be relatively diffuse rather than localized. As much as possible, limitation of immunosuppression is important in the treatment of PTLD. Rituximab is increasingly used in the treatment of PTLD when malignant cells express CD20.

Acute Lymphoblastic Leukemia

Phases of treatment for ALL include induction, consolidation, and maintenance. Induction therapy includes glucocorticoids, vincristine, asparaginase, and possibly an anthracycline. Philadelphia chromosome–positive patients have a worse prognosis and are also treated with tyrosine kinase inhibitors. Essentially all treatment protocols include CNS prophylaxis, which is administered during the induction phase. Consolidation and maintenance therapy involves the administration of further chemotherapy or, in some high-risk cases, hematopoietic cell transplantation (HCT).

Cranial radiotherapy used to be a standard component of CNS prophylaxis but induces CNS toxicity in a substantial proportion of patients. Radiation has been largely replaced by use of intrathecal chemotherapy LEVEL 2.[14] A variety of regimens have been used but most often include intrathecal methotrexate, cytarabine, and hydrocortisone. Neurotoxicity, with MRI evidence of leukoencephalopathy, has been described with high doses of intrathecal methotrexate.

Established CNS leukemia at the time of diagnosis is still commonly treated with the combination of whole-brain irradiation and intrathecal methotrexate. Given that the prognosis of adults with CNS leukemia is guarded, there may be a role for allogeneic HCT, but further research is required.

Plasma Cell Malignancies

Multiple Myeloma

An MM is a malignancy of marrow plasma cells characterized by the production of monoclonal immunoglobulins. It is the most prevalent hematologic malignancy after NHL and is particularly common in the elderly with a median onset age in the early 60s. MM has a higher incidence in African Americans and in men.

Plasma cell proliferation in the marrow interferes with the production of other hematopoietic cells, resulting in anemia and thrombocytopenia. Lytic bone lesions cause pain and make patients vulnerable to pathologic fractures. Increased bone metabolism precipitates hypercalcemia. Production of immunoglobulins by other plasma cells is impaired, resulting in hypogammaglobulinemia and impaired humeral immunity with increased vulnerability to bacterial infections. Renal failure may occur for a variety of reasons, including acute tubular necrosis from light-chain casts, glomerulonephropathy from amyloidosis, and the effects of hypercalcemia.

The various complications of MM (eg, hypercalcemia, infections, or uremia) may produce neurologic symptoms (eg, altered level of consciousness). Vertebral body fractures or plasmacytomas can cause spinal cord compression. Brain involvement is less common and may be due to plasmacytoma extension from the skull or the development of leptomeningeal myelomatosis with resultant cranial nerve palsies or spinal radiculopathies. The CNS involvement can generally be diagnosed with MRI

scans and assessment of CSF. There have been no prospective studies assessing optimal therapy of CNS involvement, but preliminary experience with adjunctive intrathecal chemotherapy and selective use of cranial irradiation has been favorable.

MM is the second most common cause of hyperviscosity syndrome (discussed in the following section). There have been an increasing number of case reports of hyperammonemic encephalopathy complicating MM. Although myeloma cells appear to produce significant quantities of ammonia, the pathogenesis remains unclear. As with other causes of hyperammonemia, patients develop lethargy, confusion, and seizures. In severe cases, there may be diffuse cerebral edema and coma. The relationship between serum ammonia concentration and clinical manifestations is imperfect, although most reported cases had markedly elevated levels. Clinical improvement has been reported with the initiation of chemotherapy. In several reports, hemodialysis was used successfully to lower ammonia levels more rapidly.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia (WM) is a form of lymphoplasmacytic lymphoma associated with production of circulating immunoglobulin M (IgM) monoclonal antibodies. Other lymphoid malignancies (eg, chronic lymphocytic leukemia), as well as monoclonal gammopathy of undetermined significance and primary amyloidosis, may also result in increased production of IgM antibodies. The WM is a rare condition with an incidence of only 3 per million population per year.

As with MM, patients may develop clinical manifestations related to tumor infiltration in hematopoietic tissues. However, most neurologic complications are related to the effects of circulating IgM. The WM is the most common cause of the hyperviscosity syndrome, which is present in as many as one-third of patients at the time of diagnosis. Serum viscosity is generally expressed in centipoises (cP), where 1 cP is the viscosity of water. Serum usually has a viscosity of 1.4 to 1.8 cP. Clinical manifestations typically occur when viscosity exceeds 4 cP and are almost always present above 6 cP. High viscosity results in sluggish blood flow and relative hypoperfusion. Consequently, patients develop blurry vision, altered mental status, and focal neurologic deficits. In severe cases, cerebral venous thrombosis or ischemic strokes may occur. Circulating proteins also interfere with platelet aggregation, leading to prolonged bleeding time and a tendency toward mucosal hemorrhage. Funduscopy classically demonstrates segmental dilatation of retinal veins as well as retinal hemorrhages or exudates. A significant proportion of patients with WM also develop a progressive sensorimotor peripheral neuropathy. The neuropathy is usually demyelinating, affects sensation to a greater degree than motor function, and targets primarily the lower extremities. Monoclonal IgM antibodies are detected by serum protein electrophoresis and direct measurement of IgM levels. Bone marrow biopsy reveals infiltration of lymphocytes with plasma cell differentiation (>10% of cells).

Hyperviscosity syndrome is a medical emergency. The need for treatment is based primarily on the presence of clinical manifestations rather than the specific serum viscosity. Apart from fluid resuscitation, patients should undergo urgent plasmapheresis using albumin rather than plasma for fluid replacement. Each treatment reduces serum viscosity by about 20% to 30% and repeated plasmapheresis is performed until symptoms have resolved. Further therapy for WM consists of appropriate chemotherapy administered together with rituximab LEVEL 2.[15]

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) is a group of hematologic malignancies involving clonal proliferation of myeloid precursor cells (destined to become granulocytes, monocytes, RBCs, or platelets). An AML may occur because of defined genetic abnormalities, as part of the natural history of myelodysplastic syndrome, or as a complication of exposure to cytotoxic drugs. An AML "not otherwise specified" is most often categorized according to the French, American, and British classification system based on the specific cell type that is implicated.

Patients with AML usually come to medical attention with manifestations attributable to pancytopenia, such as fatigue, weakness, infections, or bleeding. Leukemic infiltration of various tissues can produce additional symptoms. If the WBC is high enough, manifestations of hyperviscosity ("leukostasis") may develop, which may be severe enough to cause stupor and coma. There appears to be an increased risk of ICH for several days after the high WBC has been corrected, possibly because of reperfusion injury.

CNS leukemic involvement is uncommon at presentation and is less of a concern for AML than with ALL. It is more common with acute monocytic and myelomonocytic leukemia as well as with relapses of acute promyelocytic leukemia. In studies where lumbar puncture is routinely performed, the incidence of CNS disease approaches 20%. Additional risk factors include African American ethnicity, younger age, and a high serum LDH. Cytarabine is commonly used as part of combination chemotherapy in AML and is thought to be relatively effective at treating CNS leukemia even when clinicians are unaware that it is present. The CNS disease with AML may manifest especially with meningeal involvement and cranial neuropathies. Some patients have evidence of raised intracranial pressure with headaches, visual impairment, and papilledema. Patients may present with extramedullary granulocytic sarcomas, which sometimes develop in the brain. Other manifestations may include intracranial hemorrhage and spinal cord compression.

CNS leukemia is most often detected by lumbar puncture. There is, however, a concern that traumatic lumbar puncture could introduce leukemic cells into CSF. Traumatic lumbar puncture is more common in the presence of thrombocytopenia, such that some experts recommend only performing the procedure once the platelet count has been corrected to more than 40,000 to 50,000. Apart from the presence of blast cells, CSF protein counts are usually moderately elevated and glucose levels may be low. An MRI may be helpful in occasional patients who have intracranial mass lesions.

There have been no clinical trials to specifically direct therapy of AML involving the CNS, such that treatment strategies are largely extrapolated from experience with other malignancies. Initial intrathecal treatment usually consists of either intrathecal methotrexate or cytarabine. As with lymphoid malignancies, intrathecal therapy can be administered either by repeated lumbar puncture or an Ommaya reservoir. The dosage is reduced by about 20% when drug is delivered directly into cerebral ventricles. Treatment is usually given 2 or 3 times per week until leukemic cells have cleared and then approximately every week for 1 year. Liposomal cytarabine has the advantage that it only needs to be administered every 2 weeks initially and then monthly. Radiation therapy is reserved for refractory cases or when patients have intracranial mass lesions or cranial neuropathies.

Hematopoietic Cell Transplantation

Hematopoetic Cell Transplantation (HCT) refers to the use of high-dose preparative chemotherapy followed by the intravenous infusion of autologous or allogeneic progenitor cells. The source of transplanted cells can be bone marrow, peripheral blood, or umbilical cord blood. HCT is used primarily to treat hematologic and lymphoid cancers but occasionally also nonmalignant marrow disorders. Pretransplant preparative regimens may be myeloablative or nonmyeloablative with the goal of eradicating malignant cells. In the case of allogeneic transplantation, conditioning regimens also provide immunosuppression to prevent graft rejection. Nonmyeloablative "reduced-intensity conditioning" (RIC) regimens are used in patients who may not tolerate more intensive induction therapy. The efficacy of RIC depends in part on a graft-versus-tumor effect. Frequently used myeloablative drugs include busulfan, cyclophosphamide, and melphalan. In the treatment of lymphoma, the most common myeloablative regimen consists of combination chemotherapy with carmustine, etoposide, cytosine arabinoside, and melphalan ("BEAM"). Fludarabine is used in RIC regimens and may also be combined with lower doses of the same drugs used for myeloablation. Coadministration of total-body irradiation targets sites that may not otherwise be affected by chemotherapy. Monoclonal antibodies directed at specific antigens on bone marrow cells can be radiolabeled and used to provide directed radiation therapy, which helps avoid the adverse systemic effects of total body irradiation. Conditioning regimens are invariably complicated by the development of pancytopenia within a few days.

One of the major complications of allogeneic HCT is *graft-versus-host disease* (GVHD), which becomes more common with a greater degree of disparity in HLA matching. Calcineurin inhibitors (cyclosporine and tacrolimus), in combination with either mycophenolate or methotrexate, are used in the prevention of GVHD. T-lymphocyte depletion with antithymocyte globulin is performed in high-risk cases.

In the setting of autologous HCT, peripheral blood progenitor cells are preferred over bone marrow because this approach leads to more rapid engraftment and fewer complications. With allogeneic HCT, there seems to be little difference in survival between use of peripheral progenitor cells and bone marrow. Peripheral cells are associated with more rapid engraftment but a somewhat higher rate of GVHD. Umbilical cord blood is another widely available source of progenitor cells that is increasingly used, but it is associated with a higher rate of graft failure and delayed immune reconstitution. Engraftment typically requires between 10 days and 4 weeks, during which patients are at especially high risk for bacterial infections and require repeated RBC and platelet transfusions.

Epidemiology

Neurologic complications occur in about 15% to 20% of patients within the first 3 to 4 months after HCT. Delirium may develop at some point in as many half of patients. The risk of CNS complications is higher with allogeneic compared with autologous HCT, especially when donors are unrelated and there is a greater degree of HLA mismatch. The most common causes of CNS complications are drug toxicity and infections. Ischemic stroke and intracranial hemorrhage are relatively unusual. Some late CNS complications may be due to disease relapse.

Pathobiology

During the initial 2 to 4 weeks after HCT, before engraftment, patients are neutropenic, resulting in a relative loss of phagocytic defenses. Chemotherapy-induced mucositis enables pathogens to translocate from the gut. Patients are therefore especially vulnerable to bacterial and fungal infections, and sepsis is a common cause of nonfocal encephalopathy. Common respiratory virus (eg, influenza) and herpes simplex virus (HSV) infections may occur throughout the post-HCT course but do not usually involve the CNS. Opportunistic viruses that reactivate in the setting of impaired cell-mediated immunity, including cytomegalovirus (CMV) and varicella-zoster virus, become a concern in the postengraftment period. Patients remain vulnerable to such infections for months. Toxoplasmosis and mycobacteria are nonviral pathogens that may reactivate. During the late postengraftment period, months to years after HCT, reactivation of EBV may induce PTLD.

Because of the concerns about infection, many HCT protocols use prophylactic antimicrobials. Fluoroquinolones (eg, levofloxacin) are typically used as prophylaxis against bacteria. Acyclovir and fluconazole are the most common regimens used for prophylaxis and against HSV and fungal infections. Surveillance for CMV and *Aspergillus* species enables preemptive therapy if infection is considered to be imminent.

Clinical Manifestations, Diagnosis, and Treatment

Complications of Conditioning Drugs

Potential neurologic complications of drugs used in HCT conditioning are summarized in Table 123.3. Several drugs, especially busulfan, have been associated with development of seizures, such that some centers provide prophylaxis with antiepileptic drugs. Although data to support this practice is limited, the incidence of seizures appears to be very low with prophylaxis. Because of concerns about drug interactions, clonazepam or levetiracetam is preferred over phenytoin by some clinicians. Although less common, there have also been case reports of neurotoxicity with cyclophosphamide, melphalan, fludarabine, and cytarabine, all of which may present with encephalopathy.

Complications of Calcineurin Inhibitors

Cyclosporine and tacrolimus are widely used in the prevention of GVHD (see Table 123.3). Posterior reversible leukoencephalopathy syndrome (PRES) is the most common serious neurologic complication of calcineurin inhibitors (see also Chapter 44). This condition is characterized by vasogenic edema that preferentially (but not exclusively) involves the posterior regions of the brain. Typical manifestations of PRES include seizures, an altered or depressed level of consciousness, and visual disturbances. The diagnosis is established with MRI. Substitution with another immunosuppressive drug is generally required. Other complications that have been reported include tremors and other movement disorders, optic neuropathy, pseudotumor cerebri, akinetic mutism, plexopathy, and demyelinating lesions.

Bacterial Infections

Encephalopathy attributable to sepsis is a common neurologic complication in the early post-HCT period. However, bacterial infections specifically involving the CNS are unusual. Initial antibiotic coverage with sufficient dosing to reach the CNS needs to be broadly directed at both gram-positive and gram-negative organisms. *Listeria monocytogenes* is a pathogen that occurs particularly in immunosuppressed patients and requires additional coverage with high-dose ampicillin or, in penicillin-allergic patients, trimethoprim-sulfamethoxazole.

TABLE 123.3 Neurologic Complications of Chemotherapeutic Drugs Used in Hematopoietic Cell Transplantation

Drug	Indication	Associated Complications
Busulfan	Conditioning	Seizures
Carboplatin	Conditioning	PRES, peripheral neuropathy, ototoxicity
Carmustine	Conditioning	Delayed encephalopathy
Cyclophosphamide	Conditioning	Transient encephalopathy
Cyclosporine	GVHD prophylaxis	PRES, seizures, movement disorders, optic neuropathy, mutism, pseudotumor cerebri, polyneuropathy
Cytarabine	Systemic: conditioning Intrathecal: CNS prophylaxis	Seizures, cerebellar dysfunction, lymphocytic meningitis, cauda equine syndrome
Etoposide	Conditioning	PRES, peripheral neuropathy, acute dystonia
Fludarabine	Reduced intensity conditioning	Toxic leukoencephalopathy, PRES, retinal toxicity
Ifosfamide	Refractory lymphoma	Encephalopathy, seizures, movement disorders
Melphalan	Conditioning	Encephalopathy
Methotrexate	Systemic: conditioning Intrathecal: CNS prophylaxis, GVHD prophylaxis	PRES, necrotizing leukoencephalopathy, transient stroke-like syndrome (may have restricted diffusion), seizures, movement disorders, optic neuropathy
Sirolimus	GVHD prophylaxis	PRES, polyneuropathy
Tacrolimus	GVHD prophylaxis	PRES, seizures, movement disorders, optic neuropathy, mutism, polyneuropathy, hearing loss, demyelinating lesions

Abbreviations: CNS, central nervous system; GVHD, graft-versus-host disease; PRES, posterior reversible leukoencephalopathy syndrome.

Fungal Infections

Candida does not have a particular predilection for the CNS, but involvement may occur in the context of disseminated disease. *Candida tropicalis* is the most likely species to be implicated. It most often causes meningitis but may also produce microabscesses. The CSF WBC count is usually elevated with either a predominance of neutrophils or leukocytes. Liposomal amphotericin B is the preferred drug because it achieves relatively high CNS concentrations and has a higher rate of success compared with other agents. It can be transitioned to fluconazole after the initial 2 weeks of therapy, but a total duration of several weeks is required, depending on the clinical and radiographic course.

Severe and prolonged neutropenia, as well as GVHD, predispose patients to invasive *Aspergillus* infections, which most often appear early in the postengraftment period. The CNS involvement may occur in the context of disseminated disease or because of local spread from sinuses and has a particular predilection for the corpus callosum. Patients usually present with seizures or focal neurologic deficits. Imaging may demonstrate multiple ring-enhancing mass lesions, sometimes with concomitant infarction. The diagnosis of invasive *Aspergillus* infections can be challenging because cultures of sputum and CSF are not always positive. A positive serum galactomannan assay has a sensitivity of about 60% to 70% and specificity for invasive disease of about 90%. The sensitivity is further increased if galactomannan can be detected in a bronchoscopy sample. When feasible, histologic assessment of biopsy material can be diagnostic. The mortality associated with CNS *Aspergillus* infections is high. Voriconazole in combination with an echinocandin, as well as surgical abscess drainage when feasible, is the preferred treatment LEVEL 3.[16]

Viral Infections

Although rare, several viruses have been reported to cause encephalitis after HCT. Human herpesvirus 6 infections have been reported to occur in as many as 3% to 4% of patients undergoing allogeneic HCT, with a median posttransplant time interval of about 3 weeks. A major risk factor is the use of umbilical cord hematopoietic cells. The MRI findings, if present, are most likely to involve the temporal lobes. Other viruses tend to occur later in the course. Varicella-zoster virus reactivation is common after HCT but usually does not involve the CNS. Cases used to occur in the immediate postengraftment period. However, with use of antiviral prophylaxis, infections more often develop weeks to months later. Cases of encephalitis due to CMV, EBV, HSV, and West Nile virus have also been primarily described well after engraftment. Diagnosis of viral infections is supported by MRI findings and relevant CSF polymerase chain reaction (PCR) analysis.

Progressive multifocal leukoencephalopathy (PML) is a demyelinating condition attributable to John Cunningham (JC) virus. The PML may complicate various conditions characterized by significant immune suppression. The PML has been described after both allogeneic and autologous HCT with a median lag of about 11 months. Clinical manifestations include seizures and subacute onset of focal neurologic deficits, ataxia, and visual disturbances. The MRI shows white matter lesions, which may show contrast enhancement. The diagnosis can be made in most cases with PCR of CSF for JC virus, which has a sensitivity of about 75% to 85% and a specificity of more than 90%. Falsely negative cases can only be diagnosed definitively with brain biopsy. There is no specific therapy for JC virus. Apart from cessation of immunosuppressive agents, drugs with theoretical action against JC virus include cidofovir and mefloquine. Mirtazapine has also been administered based on the observation that JC virus uses serotonin receptors to infect cells.

Protozoal Infections

The protozoan *Toxoplasma gondii* exists in a quiescent form in some recipients of HCT and may reactivate in the postengraftment period because of impaired cell-mediated immunity.

Most patients who develop invasive disease are seropositive before undergoing transplantation. The presence of moderate to severe GVHD is a risk factor. Onset of symptoms typically occurs after about 2 to 3 months. Toxoplasmosis may present with isolated CNS involvement or as part of a disseminated infection. Clinical manifestations include fever, seizures, and a depressed level of consciousness. Extracerebral manifestations may include pneumonitis or chorioretinitis. Neuroimaging usually reveals ring-enhancing lesions. A presumptive diagnosis can be based on characteristic clinical findings in patients who have positive *Toxoplasma* serology and did not receive prophylaxis. The diagnosis can be made with CSF PCR with a high specificity but variable sensitivity. Biopsy of affected brain is usually diagnostic in patients that can safely undergo the procedure. Initial therapy consists of pyrimethamine, sulfadiazine, and leucovorin for about 6 weeks. Corticosteroids should be considered for patients with evidence of significant vasogenic edema and mass effect.

Graft-Versus-Host Disease

Acute GVHD affects primarily the gastrointestinal tract, skin, liver, eyes, and lungs; neurologic involvement is uncommon. Chronic GVHD (occurring after >100 d) involves the peripheral nervous system more often than the CNS. Conditions that have been associated with GVHD include polymyositis, immune-mediated polyneuropathy comparable to Guillain-Barré syndrome and myasthenia gravis. The CNS conditions that have been associated with GVHD include vasculitis, acute demyelinating encephalomyelitis, and aseptic meningitis. In most cases, it is unclear to what degree the GVHD is causative, and treatment does not differ from idiopathic cases.

PLATELET DISORDERS

Thrombocytopenia

After formation in the bone marrow from megakaryocytes, platelets circulate for 7 to 10 days. Thrombocytopenia is defined as a platelet count less than 150,000/μL. The risk of spontaneous hemorrhage, including intracranial hemorrhage, increases especially below 10,000 to 20,000/μL. A review of reported cases of ICH among children in the United States with immune thrombocytopenic purpura found that 90% had counts less than 20,000/μL and 75% had counts less than 10,000/μL. Excessive bleeding during surgery may be encountered below 50,000/μL. Thrombocytopenia may occur because of reduced production, increased destruction or consumption, and splenic sequestration (Figs. 123.3 and 123.4).

Prophylactic platelet transfusions are generally not recommended unless the platelet count reaches 10,000/μL. Transfusion strategies that are even more restrictive than this have been associated with a higher risk of spontaneous bleeding LEVEL 3.[17,18] The minimum platelet count required before performing lumbar puncture is not well defined but is recommended to be greater than 40,000 to 50,000/μL, particularly because the consequences of iatrogenic hemorrhage could be catastrophic. For neurosurgical procedures, counts greater than 80,000 to 100,000/μL have been suggested. A similar target seems reasonable when spontaneous ICH occurs in thrombocytopenic patients, especially in the first few hours when hematoma expansion usually occurs. The expected increment in the platelet concentration per unit transfused is about 10,000/μL. More frequent administration of lower doses may be a more efficient approach, with less overall need for allogeneic platelets compared with administration of larger doses LEVEL 1.[19] Certain causes of thrombocytopenia have other important neurologic effects and merit further discussion.

FIGURE 123.3 Computed tomography scan of a 19-year-old man who presented with acute promyelocytic leukemia, complicated by disseminated intravascular coagulation, and severe thrombocytopenia, demonstrating multiple areas of hyperdensity consistent with intracerebral hemorrhage.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura (TTP) is a clinical syndrome characterized by the presence of microangiopathic hemolytic anemia, thrombocytopenia, and various degrees of organ failure in the absence of another recognized cause (eg, malignant hypertension or scleroderma). TTP and hemolytic uremic syndrome (HUS) are likely to represent different spectrums of the same disorder, with the former classically having neurologic manifestations and the latter presenting with renal involvement. The comprehensive term *thrombotic thrombocytopenic purpura-hemolytic uremic syndrome* (TTP-HUS) reflects the overlap that occurs between these conditions. The classic "pentad" consisting of hemolysis, thrombocytopenia, fever, neurologic manifestations, and kidney failure is not required for a diagnosis of TTP-HUS and is actually not present in the majority of cases. It is possible that, over time, TTP-HUS has been recognized and treated earlier, such that progression to fulminant disease has become less common. Some patients with TTP-HUS have reduced activity of ADAMTS13, a metalloprotease responsible for cleaving von Willebrand factor (vWF). About half of patients with TTP-HUS have neurologic involvement.

Epidemiology

The incidence of TTP-HUS is about 4 to 11 cases per million population per year. About 40% of cases are idiopathic; about a third occur in the setting of various autoimmune, infectious, or malignant disorders; and the remainder is associated with various drugs, HCT, or pregnancy. A form of TTP-HUS that is particularly common in children follows diarrheal illness caused by toxin-producing enterohemorrhagic *Escherichia coli*.

FIGURE 123.4 Causes of thrombocytopenia. Abbreviations: CLL, chronic lymphocytic leukemia; DIC, disseminated intravascular coagulation; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; ITP, immune thrombocytopenic purpura; PLT, platelet; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

Pathobiology

TTP is characterized pathologically by the formation of platelet-rich thrombi in arterioles and capillaries. There is also thickening of the intima, hypertrophy of underlying smooth muscle, and deposition of fibrin. Many idiopathic cases of TTP-HUS are associated with severe deficiency of ADAMTS13 activity (<10% of normal). Reduced activity is commonly related to an inhibitory antibody. The consequent accumulation of vWF multimer promotes platelet activation and aggregation. Other mechanisms that have been implicated include relative deficiency of vascular endothelial growth factor, increased amounts of plasminogen activator inhibitor type 1, and dysregulation of complement. In patients with TTP-HUS complicating enterohemorrhagic *E coli* diarrheal illness, toxins penetrate into the circulation bound to neutrophils and then target endothelial cells. Although kidney involvement is common, it is not universal, and some patients present with neurologic manifestations.

Some chemotherapeutic agents (eg, cisplatin) and immunosuppressive drugs (eg, cyclosporine) produce direct endothelial toxicity that resembles TTP-HUS. The most common drug to be implicated in causing TTP-HUS is quinine; in this case, the pathogenesis appears to be antibody mediated. The mechanism of TTP-HUS that is occasionally associated with use of the antiplatelet agent clopidogrel is not well understood. Although the pathogenesis of TTP-HUS occurring in pregnancy is not clear, it has been noted that ADAMTS13 levels decline progressively beginning in the second trimester, which may increase vulnerability.

Autopsy specimens show similar changes in cerebral microvasculature as in other organs. Some patients develop acute ischemic strokes, but these do not usually involve large vascular territories. In a series of patients with TTP who had neurologic manifestations and underwent brain MRI scans, about a third had small ischemic strokes. When angiography is performed, large-vessel occlusion is rarely observed. By far, the most common radiographic findings are those of PRES, which was present in almost half of cases. As with other causes of PRES, the mechanism likely involves vasogenic edema induced by endothelial damage and disruption of the blood-brain barrier. Thus, when clinicians observe hypodensities on CT scans, they should not necessarily conclude that they are infarcts or that they are irreversible.

Clinical Manifestations

TTP-HUS is invariably characterized by the presence of hemolysis and thrombocytopenia. Hemolysis results in increased concentrations of serum indirect bilirubin and LDH and reductions in serum haptoglobin. Levels of LDH are often very high and can be used as a surrogate for response to therapy. The RBCs become fragmented by fibrin in the microcirculation, resulting in the formation of schistocytes, which can be visualized on peripheral blood smears. Thrombocytopenia ranges from profound to relatively mild. In patients with renal involvement, there may be some hematuria and proteinuria, although it is usually not as severe as in patients with glomerulonephritis. A minority of patients requires renal replacement therapy. The most common neurologic manifestation is altered mental status, occurring in about one-third of all patients. Seizures occur in 15% to 20%, whereas coma and strokes develop in about 10%.

Diagnosis

In patients who are anemic and thrombocytopenic, crucial diagnostic tests to assess for TTP-HUS are a peripheral blood smear, serum LDH, and bilirubin. Sepsis with disseminated intravascular coagulation produces some of the same findings as TTP-HUS but usually also causes prolongation of the prothrombin time and partial thromboplastin time (PTT) and a reduction in serum fibrinogen levels. Measurement of ADAMTS13 should be performed. A low level of ADAMTS13 activity (<10%) is a specific finding that essentially confirms the diagnosis of TTP-HUS. On the other hand, patients with TTP-HUS may not have low ADAMTS13 activity, and intermediate (10% to 50%) or normal (>50%) values should not be used as criteria to stop therapy. Patients who present with higher ADAMTS13 activity do, however, appear less likely to relapse after initial therapy.

If patients have acute kidney injury that does not response readily to fluid resuscitation, a kidney biopsy can be considered and may be diagnostic. Potential causes of TTP-HUS should be sought. If there is a history of diarrhea, stool should be assessed for the presence of toxin-producing bacteria, especially *E coli* O157:H7. In women of appropriate age, pregnancy should be ruled out. Clinicians should determine whether patients have been taking various drugs that have been associated with TTP-HUS.

Management

In original descriptions of TTP-HUS, mortality was very high. Outcomes have improved markedly with use of plasma exchange (PLEX) LEVEL 1.[20] It is thought that one of the main mechanisms of PLEX is the removal of inhibitory antibodies targeting ADAMTS13 and concomitant replacement with plasma. However, the efficacy of PLEX is not necessarily limited to patients who are ADAMTS13 deficient. It is therefore reasonable to initiate PLEX even before the diagnosis is entirely certain. The benefit of PLEX is less clear in TTP-HUS associated with other conditions compared with idiopathic cases. The PLEX is usually performed daily until platelet counts have normalized and evidence of hemolysis (high LDH and presence of schistocytes) is abating. Because of the presumed autoimmune etiology of idiopathic TTP-HUS, some experts recommend treatment with corticosteroids. Preliminary data suggest rituximab may be beneficial in refractory cases. When TTP-HUS occurs in pregnancy, it may be difficult to distinguish from other obstetrical syndromes, including preeclampsia and HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, such that early delivery should be considered. The PLEX is safe during pregnancy and should not be withheld.

Treatment of neurologic complications is largely supportive. Usual measures aimed at preventing and treating cerebral edema should be implemented. Neurologic involvement in TTP-HUS is a clear risk factor for failure to respond to therapy and worse outcomes. Longer term follow-up of patients who survive TTP-HUS reveals that many have persistent neurocognitive deficits. Strokes occur in about 10% to 15% of patients and are predicted by lower ADAMTS13 activity levels during remission. Future research should investigate whether modifications in the care of patients with TTP-HUS might prevent such deficits.

Heparin-Induced Thrombocytopenia

Heparin is one of the most common medications known to induce thrombocytopenia. Immune-mediated heparin-induced thrombocytopenia (HIT) occurs after at least 5 days of heparin exposure and is associated with a high risk of thrombotic (rather than hemorrhagic) complications, including stroke. The incidence is approximately 2% to 3% with more than 5 days of heparin exposure. The risk is higher with unfractionated rather than low molecular weight heparin. Onset beyond 2 weeks of heparin exposure is relatively uncommon.

Pathobiology and Clinical Features

The HIT is due to the formation of antibodies targeting the heparin-platelet factor 4 complex. When antibodies bind to this complex on platelet surfaces, they induce platelet activation and aggregation, which in turn promotes thrombin generation. Consumption and clearance of activated platelets causes the platelet concentration to fall. The risk of thrombosis over the 4 weeks following the diagnosis of HIT is greater than 50%. Most patients with HIT have relatively mild thrombocytopenia (rarely <20,000/μL). The development of lower extremity deep venous thrombosis is the most common complication of HIT, but arterial thrombosis can occur. Neurologic complications, primarily arterial ischemic strokes and to a lesser degree cerebral venous thrombosis, have been reported to occur in 3% to 9% of patients with established HIT.

Diagnosis

A clinical scoring system, the 4T score, can be used to assess the pretest probability that a patient could have HIT (Table 123.4). Patients are assigned 0 to 2 points for each of four variables: the degree of thrombocytopenia, the timing of the platelet drop, the development of thrombosis, and the presence of alternative causes of thrombocytopenia. A score of 0 to 3 indicates a low risk of HIT and provides justification to not pursue additional testing. A score of 4 to 5 suggests an intermediate risk and 6 to 8 indicates a high risk. Heparin-platelet factor 4 complexes can be detected with enzyme-linked immunosorbent assay with a high sensitivity but somewhat lower specificity. The gold standard test, with sensitivity and specificity greater than 95%, is the carbon 14-serotonin release assay, which is only performed at specialized centers.

Treatment

When HIT is suspected, all heparin must be discontinued, including that used for deep venous thrombosis prophylaxis or to flush venous or arterial catheters. If the suspicion for HIT is at least moderate, the risk of thrombosis is sufficiently high to justify therapeutic anticoagulation with an alternative drug that does not cross-react with heparin. Appropriate parenteral alternatives include the direct thrombin inhibitors argatroban, bivalirudin, and danaparoid as well as the pentasaccharide fondaparinux.

TABLE 123.4 The 4T Score in the Diagnosis of Heparin-Induced Thrombocytopenia[a,b]

Variable	2 Points	1 Point	0 Point
Thrombocytopenia severity	Platelet fall >50% and platelet nadir ≥20	Platelet fall 30%-50% or platelet nadir 10-19	Platelet fall <30% or platelet nadir <10
Timing of platelet count reduction	Clear onset day 5-10 or ≤1 d with prior heparin exposure past 30 d	Consistent with day 5-10 fall but not clear; onset after day 10; or fall ≤1 d with prior heparin 30-100 d ago	Platelet fall <4 d without recent exposure
Thrombosis	New thrombosis, skin necrosis	Progressive or recurrent thrombosis	None
Thrombocytopenia alternative causes	None apparent	Possible	Definite

[a]Score of 0-3: <1% chance of heparin-induced therapy (HIT); score of 4-5: 10%-15% chance of HIT; score of 6-8: >50% chance of HIT.
[b]Data from Cuker A, Gimotty PA, Crowther MA, Warkentin TE. Predictive value of the 4Ts scoring system for heparin-induced thrombocytopenia: a systematic review and meta-analysis. *Blood*. 2012;120(20):4160-4167.

Treatment with warfarin can be initiated after the platelet count has risen to more than 150,000/μL. Warfarin should overlap with parenteral anticoagulation for at least 5 days and should then be continued with a target international normalized ratio (INR) of 2 to 3 for 3 months in the setting of thrombosis and 4 to 6 weeks for HIT without thrombosis. Increasing evidence support the use of direct oral anticoagulant (DOAC) drugs (apixaban, rivaroxaban, or edoxaban) in the treatment of HIT, either after a parenteral agent or even as initial therapy.

Impaired Platelet Function

Platelet function may be impaired by numerous genetic disorders and acquired medical conditions, including uremia, plasma cell dyscrasias, advanced liver disease, and myeloproliferative disorders. More often, platelet dysfunction is iatrogenic from antiplatelet drugs used in the prevention and treatment of cardiovascular disease.

Many patients who develop spontaneous ICH or subdural hematomas are receiving antiplatelet drugs. The degree of hematoma expansion over the initial few hours after intracranial hemorrhage is a crucial predictor of outcome. Although literature is conflicting, numerous studies have suggested that the degree of expansion and the chance of poor outcome is greater among patients receiving antiplatelet drugs. Aspirin (acetylsalicylic acid [ASA]) is the most common agent and works by inhibiting the effects of cyclooxygenase-1 in converting arachidonic acid to prostaglandin H_2, thereby reducing levels of thromboxane A_2, an inducer of platelet aggregation. The antiplatelet effects of ASA are irreversible and last for the life span of the platelet. Clopidogrel is a thienopyridine drug, which works by permanently modifying platelet ADP receptors, thereby inhibiting platelet aggregation. The addition of clopidogrel to ASA is particularly important for patients who have undergone percutaneous coronary interventions. Prasugrel and ticagrelor are newer antiplatelet drugs that work on the same receptor as clopidogrel and may have a greater degree of antiplatelet effect and in turn cause a slightly higher risk of bleeding.

Newer assays enable point-of-care assessment of platelet function, thereby allowing the effects of antiplatelet drugs to be rapidly measured. This information could potentially be used in therapeutic decision making.

Platelet transfusions can improve platelet activity. However, the Platelet Transfusion in Cerebral Hemorrhage trial found that use of platelet transfusions in patients with ICH who had been using antiplatelet drugs did not attenuate hematoma expansion and appeared to, in fact, result in worse outcomes LEVEL 1.[21] Of note, few patients in the Platelet Transfusion in Cerebral Hemorrhage trial were receiving dual antiplatelet therapy or newer, more potent, antiplatelet drugs, such that further studies are justified.

Desmopressin improves platelet activity by promoting the release of vWF from endothelium. Its use among ICH, SAH, or TBI patients receiving antiplatelet drugs has been associated with less hematoma expansion, but evaluation in randomized controlled trials is needed.

Thrombocytosis

Thrombocytosis refers to an elevation in the concentration of platelets and is usually defined using a threshold of 450,000/μL. Thrombocytosis may be "reactive" in response to a systemic condition or may be a manifestation of ET or another myeloproliferative disorder ("autonomous thrombocytosis"). A reactive etiology (eg, inflammation, tissue damage, anemia) is much more common, even when thrombocytosis is extreme (>1,000,000/μL). Clinical manifestations, including vasomotor symptoms (eg, headache and visual disturbances) as well as thrombotic or hemorrhagic complications, occur with autonomous thrombocytosis and are uncommon with reactive thrombocytosis.

Essential Thrombocythemia

ET is a clonal myeloproliferative disorder characterized by an elevated platelet count. There is no specific diagnostic test for ET and excluding reactive thrombocytosis and other myeloproliferative disorders makes the diagnosis. The ET is associated with an increased risk of thrombosis, including stroke. The median age of patients diagnosed with ET is about 60 years, and it is more common in women.

Pathobiology

Numerous factors contribute an increased risk of thrombosis, including activation of platelets, resistance to the effects of endogenous coagulation inhibitors (protein C and S), increased levels of thrombomodulin, and activation of leukocytes. Risk factors for thrombosis include a previous history of thrombotic events, the presence of the JAK2 mutation, leukocytosis, and other cardiovascular risk factors.

Clinical Manifestations

Many patients are asymptomatic at the time of diagnosis. The most common complaints are vasomotor symptoms and erythromelalgia. The risk of thrombosis is not directly related to the degree of platelet elevation. The risk of thrombotic events over 15 years is about 20%, and stroke develops in about 10% to 15% of patients. A small proportion of patients eventually develop AML or myelofibrosis.

Diagnosis

Bone marrow aspirates and biopsies demonstrate hyperplasia of megakaryocytes. Cytogenetic studies reveal absence of the Philadelphia chromosome (characteristic of chronic myelogenous leukemia). About half of patients with ET will have the JAK2 mutation. To be diagnosed with ET, there should be no evidence of myelofibrosis and a normal RBC mass.

Management

Patients at low risk for thrombosis include those younger than 60 years, with no previous events and a platelet count less than 1,000,000/μL. These patients do not necessarily require treatment. Vasomotor symptoms and erythromelalgia often respond to treatment with low-dose ASA. Patients with previous thrombosis and those who are older than 60 years are generally treated with a combination of ASA and hydroxyurea, with an initial dose of 15 mg/kg/d, adjusted to achieve a target platelet count less than 600,000/μL LEVEL 2.[22] Achieving counts less than 400,000/μL may further reduce the risk of subsequent thrombosis.

COAGULATION DISTURBANCES

Coagulation disturbances develop when there is insufficient production, increased consumption, or inhibition of clotting factors. Apart from rare congenital deficiencies of specific clotting factors (eg, factor VIII with hemophilia A), reduced production of clotting factors occurs largely because of liver disease,

vitamin K deficiency, or the use of the vitamin K antagonist warfarin. Other anticoagulants work primarily by inhibiting thrombin. Consumption of clotting factors occurs with disseminated intravascular coagulation and massive hemorrhage. Coagulation disturbances are of interest to neurologists and neurosurgeons because of their association with intracranial hemorrhage.

Normal Coagulation

When endothelium is damaged, there is immediate activation and aggregation of platelets. Apart from forming an initial barrier to bleeding, the platelet plug also provides the phospholipid template upon which coagulation can proceed. Tissue factor is a membrane protein that is expressed by subendothelial cells and interacts with circulating factor VII, which in turn activates factor X. This process is further amplified by factors VIII and IX. Activated factor X, together with factor V, converts prothrombin to thrombin, which in turn promotes conversion of fibrinogen to fibrin. Thrombin also has a positive feedback effect, whereby it further activates platelets, factor VIII, and factor XI (Fig. 123.5).

To avoid unregulated clotting, there exist a number of natural anticoagulant mechanisms. Antithrombin is a protease inhibitor that blocks the activity of factor X. Thrombomodulin is a protein on the surface of endothelial cells that inhibits thrombin and activates protein C, which together with protein S inactivates factors V and VIII. The endothelial enzyme tissue plasminogen activator (tPA) stimulates the conversion of plasminogen to plasmin, which is responsible for cleaving cross-linked fibrin.

Impaired Coagulation

Warfarin-Induced Intracranial Hemorrhage

Although increasingly replaced by newer oral anticoagulants, warfarin has long been used to reduce the risk of thromboembolic complications in patients with atrial fibrillation, to prevent valve thrombosis in patients with mechanical heart valves, and as treatment of venous thromboembolism. Warfarin antagonizes the formation of vitamin K–dependent clotting factors (II, VII, IX, and X) in the liver. Its effect on clotting is measured by the prothrombin time and the measurement is standardized using the INR. For most conditions, the target INR is 2 to 3. The risk of intracranial hemorrhage with warfarin has been in the range of 1% in clinical trials but is somewhat higher in usual practice where patients may not be as carefully selected and the INR not as carefully monitored.

Hematoma expansion is more pronounced and outcomes worse among patients with warfarin-induced ICH. Although fresh frozen plasma (FFP) reverses the effects of warfarin, the time required for cross-matching, thawing, and administering 20 to 40 mL/kg of fluid results in major delays. The INR can be corrected more rapidly with the use of four-factor prothrombin complex concentrate (PCC), which contains vitamin K–dependent clotting factors in a relatively small volume of fluid that can be administered over a few minutes LEVEL 4.[23] There has been one small clinical trial specifically in patients with intracranial hemorrhage, which confirmed more rapid correction of the INR with PCC, with a suggestion also of less hematoma expansion LEVEL 2.[24] Neurocritical Care Society, American Society of Hematology, and American College of Chest Physician guidelines all recommend preferential use of four-factor PCC rather than FFP or recombinant factor VIIa. The optimal dose of PCC remains unclear but is generally recommended to include 25 to 50 IU/kg of factor IX activity. Higher doses may be preferable with more pronounced initial elevation of the INR. Repeat INR testing soon after completion of PCC administration and then every 6 to 8 hours for the next 24 to 48 hours is recommended. Intravenous vitamin K (10 mg) should also be administered to help avoid a subsequent increment in INR after initial correction.

FIGURE 123.5 Traditional model of the coagulation cascade with extrinsic **(left)** and intrinsic **(right)** pathways. Although this laboratory model is useful to understand the factors, which may influence coagulation times (prothrombin time, **left**; partial thromboplastin time, **right**), it is not a physiologic model that describes exactly how coagulation functions in vivo. Abbreviations: HMWK, high molecular weight kininogen; PK, prekallikrein; PL, phospholipid.

Reversal of Novel Oral Anticoagulants

Several DOACs have been demonstrated to be equally or more efficacious than warfarin in the prevention of stroke among patients with atrial fibrillation and in the treatment of venous thromboembolism, with a comparable or lower risk of intracranial hemorrhage. Dabigatran is a direct thrombin inhibitor, whereas rivaroxaban, apixaban, and edoxaban are factor X_a inhibitors. The PTT and INR do not measure the effects of these agents. Measurement of the thrombin time or ecarin clotting time, if available, provides a better reflection of the anticoagulant effect of dabigatran. Anti–factor X_a activity can be measured to assess the anticoagulant effect of factor X_a inhibitors.

Significant early hematoma expansion and poor outcomes are common when ICU occurs in the context of DOAC use, although outcomes are generally no worse than with warfarin-associated ICH. Outcomes from DOAC-related ICH may improve with increasing availability of rapid reversal agents. Idarucizumab is a monoclonal antibody fragment that binds dabigatran with much greater affinity than thrombin, thereby neutralizing its anticoagulant effect within minutes. Andexanet alfa is a recombinant factor X_a decoy protein that binds factor X_a inhibitors. It is administered as a bolus and then subsequent 2-hour infusion and rapidly reduces anti–factor X_a activity. The degree to which these novel agents attenuate hematoma expansion has not been well studied. The PCC or activated PCC (factor VIII inhibit bypassing activity) may also have some limited efficacy for reversing the effects of both direct thrombin and factor X_a inhibitors and should be considered when reversal agents are not available.

Bleeding Associated With Thrombolytic Therapy

When tPA is administered to treat acute ischemic stroke, the risk of intracranial hemorrhage is in the range of 3% to 7%. This rate is 1% to 2% when tPA is used for other conditions, such as myocardial infarction or pulmonary embolism. Apart from discontinuation of the infusion, patients should receive 10 units of cryoprecipitate to increase fibrinogen levels because there is some evidence that hemorrhagic infarction after tPA is associated with a systemic consumption coagulopathy and fibrinogen depletion. Fibrinogen concentrate could be used instead of cryoprecipitate, but there is relatively little published experience. There is also a theoretical benefit from antifibrinolytics like tranexamic acid or ε-aminocaproic acid, and they can be administered more rapidly than cryoprecipitate or fibrinogen concentrate. Previous American Heart Association guidelines have recommended platelet transfusions because platelet aggregation may be altered by tPA, but there is little evidence to support this practice, and it is not recommended in Neurocritical Care Society guidelines.

Bleeding Associated With Unfractionated or Low Molecular Weight Heparin

Unfractionated heparin exerts its anticoagulation effect by binding the natural anticoagulant antithrombin III and inducing a conformational change that potentiates inactivation of factor X_a and thrombin. Intracranial hemorrhage is very uncommon with heparin. The effects of heparin can be reversed by protamine, which is generally administered at a dose of 1 unit for every 100 units of heparin administered in the past 2 to 3 hours, to a maximum of 50 mg. Low molecular weight heparins have a similar mechanism, but protamine is less effective as a reversal agent, although its use is still recommended in cases of intracranial hemorrhage. Preliminary experience with andexanet alfa suggests that it is effective at reversing the anti–factor X_a activity of enoxaparin.

Hypercoagulable States

Familial Thrombophilia

The possibility of thrombophilia should be considered, especially when stroke occurs in children and young adults. It should also be pursued when there are recurrent thromboembolic events or when there is a strong family history. Several familial conditions cause deficiencies or dysfunction of naturally occurring anticoagulants, including protein S, protein C, antithrombin III, and factor V. A mutation of prothrombin (factor II) has been identified as a risk factor for both ischemic strokes and cerebral venous thrombosis, especially with concomitant use of oral contraceptives.

Antiphospholipid Antibody Syndrome

The antiphospholipid syndrome (APLS) is a condition characterized by arterial or venous thrombosis and/or pregnancy morbidity, occurring in combination with persistently detectable antiphospholipid (APL) antibodies. It is of interest to neurologists primarily because it predisposes patients to ischemic stroke and cerebral venous thrombosis and is also associated with neuropsychiatric manifestations and cognitive decline.

Epidemiology

Approximately half of patients have "primary" APLS, whereas the remainder has either systemic lupus erythematosus or another connective tissue disorder. The APLS is more common in women and has a mean age at diagnosis of 40 to 45 years. Ischemic strokes occur in 10% to 20% and TIAs in about 5% to 15% of patients meeting established criteria for APLS.

Pathobiology

There are several mechanisms whereby APL antibodies may contribute to an increased risk of thrombosis, including interference with natural anticoagulant mechanisms (eg, inhibition of protein C and antithrombin III activity), activation of platelets and endothelial cells, and triggering of the complement cascade. Some cases of ischemic stroke in APLS develop because of in situ thrombosis, whereas others are cardioembolic. Valvular cardiac abnormalities that can be detected by transesophageal echocardiography range from thickening of valve leaflets to the development of frank vegetations (nonbacterial endocarditis). The mitral valve is affected more often than the aortic valve. Spontaneous echo contrast is also sometimes found in the left atrium, but a definitive association with stroke risk has not been established.

Clinical Manifestations

Prospective studies have shown that APL antibodies can be detected in a sizable proportion of patients diagnosed with ischemic strokes. However, in some cases, the antibodies are only transiently and slightly elevated and therefore not consistent with true APLS. Studies are somewhat conflicting regarding the question of whether the presence of detectable APL antibodies purports an increased risk of subsequent stroke. The association with stroke appears to be strongest and most definitive in young women and when more than one type of APL antibody is elevated.

Venous thrombosis is more common than arterial thrombosis with APLS. The possibility of APLS should always be considered

in patients presenting with idiopathic cerebral venous thrombosis. A significant proportion of patients with APLS develop cognitive deficits even without previously diagnosed strokes. The specific mechanism is not well understood, although MRI scans commonly reveal white matter disease. Apart from pregnancy loss and thrombosis, APLS can also present in some cases with microangiopathy, similar to TTP-HUS. Catastrophic APLS refers to a small subset of patients who develop multiorgan failure as a result of widespread thrombosis; this occurs in less than 1% of patients.

Diagnosis

APLS should be considered in the setting of idiopathic episodes of thrombosis, recurrent pregnancy loss, unexplained thrombocytopenia or abnormal PTT, and thrombotic microangiopathy. The APL antibody titers should not be routinely assessed in all patients with ischemic strokes. Diagnostic workup for APLS consists of enzyme-linked immunosorbent assay testing for immunoglobulin G and IgM anticardiolipin and anti–β2-glycoprotein antibodies as well as testing for a lupus anticoagulant. If positive, these assays should be repeated after at least 12 weeks for confirmation. Criteria for catastrophic APLS have been proposed and include a history of APLS, thrombosis in three or more organ systems within a week, biopsy confirmation of microthrombosis, and exclusion of other causes of thrombosis. Patients are considered to have definite catastrophic APLS if all four criteria are met. Patients have probable APLS if there are only two organs involved, if the only missing criterion is histopathology, or if the time frame of recurrent thrombosis exceeds 1 week but is less than 1 month.

Management

Optimal treatment of stroke in the context of APLS is somewhat controversial. American Stroke Association guidelines state that antiplatelet drugs remain appropriate treatment for patients with cryptogenic ischemic stroke or TIA in whom APL antibodies are detected (class 2b, level of evidence B). The rationale for this recommendation is that the largest prospective series have not demonstrated a difference in the rate of subsequent thrombotic events based on whether or not APL antibodies are present. On the other hand, the guidelines also state that oral anticoagulation is appropriate therapy for patients in whom a diagnosis of APLS is confirmed, which would be the case for any patient with stroke in whom repeat antibody testing after 12 weeks is confirmatory. In several retrospective series of confirmed APLS, treatment with aspirin had limited efficacy.

Despite availability of newer oral anticoagulants, most experience treating APLS has been with warfarin. Recent clinical trials suggest that DOACs are less effective than warfarin at treating thrombosis in the context of APLS LEVEL 1.[25,26] As in other settings, the goal INR is 2 to 3. Although some older literature advocated for more intensive anticoagulation (INR 3-4), subsequent clinical trials did not demonstrate any advantage to justify the higher risk of hemorrhage LEVEL 1.[27,28] For patients with thrombosis in the setting of APLS, indefinite anticoagulation is recommended. For patients with other reasons for a thrombotic event, in whom the elevation in APL antibody titers is mild or transient, cessation of therapy after a few months can be considered.

For patients with APL antibodies and risk factors for stroke, it is reasonable to administer antiplatelet drugs as primary prophylaxis. Antiplatelet therapy is also recommended for patients with APL antibodies and neuropsychiatric manifestations but no clear evidence of a stroke. However, identification of APL antibodies alone is likely not sufficient justification for regular use of antiplatelet therapy. There are no randomized trials specifically in patients meeting criteria for catastrophic APLS. Retrospective series suggest that mortality may be lower when patients are treated not only with anticoagulation but also with corticosteroids and PLEX.

Hepatic Disease and the Brain 124

Charles L. Francoeur and Stephan A. Mayer

KEY POINTS

1. Hepatic encephalopathy associated with chronic cirrhotic liver disease and the syndrome of encephalopathy with brain edema caused by fulminant acute liver failure are two distinct entities.
2. Cirrhotic hepatic encephalopathy is frequent, with nonspecific signs and symptoms ranging from barely perceptible to coma, and is caused by elevated levels of ammonia.
3. Lactulose and rifaximin are the only evidence-based treatments for cirrhotic hepatic encephalopathy.
4. The most frequent cause of acute liver failure leading to encephalopathy is drug toxicity, led by acetaminophen poisoning.
5. The picture of fulminant hepatic encephalopathy is dominated by cerebral edema, and intracranial pressure monitoring is sometimes required.
6. High-volume plasma exchange is the only therapy shown to improve transplant-free survival in fulminant hepatic encephalopathy, whereas orthotopic liver transplantation is the only definitive treatment when liver function does not recover.

INTRODUCTION

Neurologic manifestations of liver disease have been recognized for centuries. The liver is indispensable in its functions of synthesis, metabolism, and detoxification, and its dysfunction can cause problems ranging from subtle neuropsychiatric finding to rapid death. Tremendous advances in our understanding of the pathophysiology and in available treatments now allow for better outcomes. In this chapter, we focus on two distinct clinical presentations of hepatic disease: hepatic encephalopathy (HE) associated with chronic cirrhotic liver disease and the syndrome of encephalopathy and brain edema caused by fulminant acute liver failure (ALF).

HE associated with cirrhosis is a neuropsychiatric syndrome ranging from barely detectable changes to profound coma. It often presents in an episodic and recurrent fashion, can be precipitated by extrinsic factors, and is graded according to the West Haven scale (Table 124.1). As a general rule, the severity of the encephalopathy is proportional to the underlying severity of liver disease. ALF, on the other hand, is a less common but highly lethal entity. Core components include the acute onset of hepatocellular dysfunction, which triggers a different set of complications dominated by cerebral edema with intracranial hypertension, unregulated systemic inflammation, and multisystem organ failure.

TABLE 124.1 West Haven Hepatic Encephalopathy Grading Scale

Grade	Description
Minimal	• Psychometric or neuropsychological alterations of tests exploring psychomotor speed/executive functions or neurophysiologic alterations without clinical evidence of mental change
1	• Trivial lack of awareness • Shortened attention span • Impaired performance of addition • Euphoria or anxiety
2	• Lethargy or apathy • Minimal disorientation for time or place • Subtle personality change • Inappropriate behavior • Impaired performance of subtraction
3	• Somnolence to semistupor, responsive to verbal stimuli • Confusion • Gross disorientation, bizarre behavior
4	• Coma (unresponsive to verbal or noxious stimuli)

CIRRHOSIS AND HEPATIC ENCEPHALOPATHY

Epidemiology

In 2017, chronic liver disease was the 12th leading cause of death in the United States accounting for more than 38,000 deaths and over 100,000 hospitalizations. Those figures are probably an underestimate and the prevalence is steadily increasing. Hepatitis C patients, typically born between 1945 and 1965, are contributing to a large number of new cases, and the obesity epidemic accounts for an increase in nonalcoholic fatty liver disease.

The less severe form of neurologic impairment, minimal hepatic encephalopathy (MHE), afflicts between 60% and 80% of cirrhotic patients. Often qualified as "subclinical," MHE is nonetheless a tremendous social burden with the majority of patients being unfit to drive and half of them unable to keep a permanent job.

Overt HE occurs in 30% to 45% of cirrhotic patients. It is responsible for the bulk of hospitalization days attributed to cirrhosis and its complications. Depending on the time course, it is subdivided into episodic, recurrent (6 mo or less between episodes), or persistent (behavioral alterations that are always present).

Pathobiology

Causes of chronic liver damage are numerous (Table 124.2), and the final common pathway is cirrhosis defined by parenchymal fibrosis with hepatic architecture distortion and the formation of regenerative nodules. The associated complications are related to a loss of synthetic and metabolic functions, relative

TABLE 124.2 Causes of Cirrhosis

• Alcoholic liver disease
• α_1-Antitrypsin deficiency
• Autoimmune hepatitis
• Celiac disease
• Chronic viral hepatitis (hepatitis B and C)
• Hemochromatosis
• Infections (eg, brucellosis, syphilis, echinococcosis, schistosomiasis)
• Medication (eg, isoniazid, methotrexate)
• Nonalcoholic fatty liver disease
• Polycystic liver disease
• Primary and secondary biliary cirrhosis
• Primary sclerosing cholangitis
• Veno-occlusive disease (including Budd-Chiari syndrome)
• Wilson disease

immunosuppression, and portal hypertension often associated with portosystemic shunting.

Most of the existing evidence points to ammonia (NH_3) as the main culprit behind HE. It is generated from glutamine by the enterocytes and from catabolism of nitrogenous products (proteins and urea) by colonic bacteria. Detoxification normally takes place in the liver through the conversion of NH_3 to urea and glutamine, basically reversing what took place in the digestive tract. Cirrhosis and portosystemic shunting bypasses this process, allowing systemic levels of NH_3 to rise, which easily crosses the blood-brain barrier (BBB) by diffusion and ion channels. Once in the brain, NH_3 is taken up by astrocytes, where it triggers oxidative stress, increases intracellular calcium, induces mitochondrial dysfunction, and activates nuclear factor κB and an inflammatory response. Some data suggest that severity of HE correlates more with inflammatory indices than with NH_3 levels. Many other molecules have been implicated in the pathobiology of HE, such as neurosteroids. Synthetized by astrocytes and microglia, they appear to upmodulate the γ-aminobutyric acid type A receptors leading to the clinically obvious increased γ-aminobutyric acid-ergic tone (depression of central nervous system function) seen in HE.

Clinical Features

Cirrhosis

Compensated cirrhotic patients may be asymptomatic, but eventually, most will develop one of the myriad of possible clinical manifestations as the disease progresses (**Fig. 124.1**). They may report nonspecific symptoms like anorexia, weight loss, fatigue, and weakness. They often have a low blood pressure, and they may present with jaundice, pruritus, severe muscle cramps, or abdominal distention from ascites.

Classically, cirrhotic patients are classified according to the Child-Turcotte-Pugh score. Designed 30 years ago to predict outcome after surgery for portal hypertension (**Table 124.3**) (http://www.mdcalc.com/child-pugh-score-for-cirrhosis-mortality), it is now used to grade clinical severity and follow the evolution of most patients. Alternatively, the Model for End-Stage Liver Disease (MELD) score evaluates serum creatinine, bilirubin, and international normalized ratio (INR) to predict 3-month mortality following transjugular intrahepatic portosystemic shunt (TIPS) procedures (http://www.mdcalc.com/meld-score-model-for-end-stage-liver-disease-12-and-older/). The MELD score is also currently used to prioritize candidates for liver transplantation scaled from 6 (less ill) to 40 (gravely ill).

Minimal Hepatic Encephalopathy

Patients with MHE, by definition, have no clinically detectable abnormalities at the bedside but manifest clear deficits on psychometric testing. They usually reveal impairment of vigilance, alertness and orientation, executive functions, working memory, learning processes, visuospatial coordination, and reaction time. When looked at closely, daily functioning is usually impaired in all spheres. They have a higher risk of car accidents with less than 20% of them fit to drive. Verbal ability is characteristically unimpaired.

Overt Hepatic Encephalopathy

Overt hepatic encephalopathy (OHE) can manifest itself from subtle clinical signs to profound coma. As it sets in, one of the earliest manifestations is classically a change in the sleep pattern (usually hypersomnia). Once it progresses, behavioral changes such as apathy, anxiety, and irritability appear. Attention span diminishes and short-term memory becomes impaired.

FIGURE 124.1 Common complications of cirrhosis. Abbreviation: GI, gastrointestinal.

TABLE 124.3 Child-Turcotte-Pugh Score[a]

	1	2	3
Bilirubin	<2 mg/L	2-3 mg/L	>3 mg/L
Albumin	>3.5 g/L	2.8-3.5 g/L	<2.8 g/L
INR	<1.7	1.7-2.2	>2.2
Ascites	No ascites	Ascites, medically controlled	Ascites, poorly controlled
Encephalopathy	No encephalopathy	Encephalopathy, medically controlled	Encephalopathy, poorly controlled

Abbreviation: INR, international normalized ratio.
[a]Interpretation: 5 to 6 points, child class A; 7 to 9 points, child class B; 10 to 15 points, child class C.

Patients sometimes suffer from visual perception disturbances, both as a result of cortical and retinal dysfunction, with visual agnosia, macropsia, spatial disorientation, and problems with visuospatial construction. Visual hallucinations can occur. Neuromuscular impairments include ataxia, dysarthria, hyperreflexia, and extensor plantar responses. Asterixis, although not pathognomonic, was first described in HE patients. This "flapping tremor" is a negative myoclonus characterized by brief interruptions of sustained voluntary muscle contractions causing loss of postural tone. It is usually bilateral, nonrhythmic, and with a frequency of 3 to 5 Hz. It can be elicited by hyperextension of the wrists but is also seen in the feet, tongue, or eyelids. Parkinsonian features are at times prominent with tremor, rigidity, bradykinesia, hypomimia, and slowness and monotony of speech. Focal deficits have been described but are rare. As patients deteriorate, the most striking feature is the mental status change from lethargy to stupor and coma. Unlike fulminant acute liver failure, however, brain swelling is not a feature of OHE from cirrhosis: The coma is metabolic in nature. At the point of coma, most patients are hyperventilating and have loss of deep tendon reflexes. Seizures are unusual. Mental status and motor changes do not always progress in a synchronized fashion.

Hepatic Myelopathy

Another well-described, long-term neurologic complication of cirrhosis is hepatic myelopathy. It is characterized by severe spastic paraparesis with minimal sensory involvement. Spasticity and weakness usually affect the lower limbs more severely and are progressive. It is caused by symmetric demyelination of the lateral pyramidal tracts. It does not respond to NH_3-lowering therapy, although some improvement might follow liver transplantation.

Persistent Hepatic Encephalopathy

Often preceded by multiple episodes of OHE, a chronic and largely irreversible syndrome characterized by dementia, dysarthria, gait ataxia, intention tremor, and choreoathetosis might appear. This persistent form of HE, previously referred to as *acquired hepatolenticular degeneration*, afflicts 4% of cirrhotic patients. It does not respond to standard therapies.

Diagnosis

Minimal Hepatic Encephalopathy

MHE diagnosis cannot be made at the bedside with usual examination techniques and requires neuropsychometric or neurophysiologic testing. Numerous tests have been designed but their use is limited as many are cumbersome, time consuming, and correlation is poor among them. Another issue is that they are nonspecific. For example, they cannot distinguish between neurologic abnormalities attributable to alcohol abuse and those caused by hepatic dysfunction. The reader is referred to the "Suggested Readings" section for a comprehensive description and critical analysis of available tests.

Overt Hepatic Encephalopathy

The diagnosis of OHE is made with the compatible clinical picture in the context of cirrhosis after exclusion of plausible alternative explanations. It is graded according to the West Haven criteria (see Table 124.1). The majority of OHE episodes are not spontaneous and rather precipitated by an event, and the absence of such cause in the setting of altered mental status should alert the clinician for other organ failures. Although blood NH_3 level per se does not allow staging or prognostication in chronic liver disease, a normal level puts the diagnosis of OHE in question. Brain imaging does not help in diagnosis but is used to rule out other pathologies, such as intracerebral hemorrhage, which is 5 times more prevalent in this population.

Treatment

Minimal Hepatic Encephalopathy

MHE rarely presents in clinical practice as a medical complaint and has not been widely evaluated in clinical trials. Several lines of evidence suggest a benefit on cognitive function and quality of life when MHE patients are treated with lactulose and rifaximin, as discussed in the following text.

Overt Hepatic Encephalopathy

OHE management focuses on identification and correction of the precipitating factor, exclusion of alternative causes for mental status changes, and measures to lower blood levels of NH_3 (Table 124.4), all the while supporting the patient appropriately.

Identification of the precipitating factor is paramount because its specific treatment is central to recovery. Precipitants are not always obvious and a careful history, physical examination, and appropriate laboratory tests are required. The most common causes are infection (especially spontaneous bacterial peritonitis and urinary tract infection), alcohol abuse, gastrointestinal bleeding, and iatrogenic insults such as dehydration from diuretics or lactulose, or oversedation from benzodiazepines or opiates.

The mainstay of NH_3-lowering therapy is administration of the nonabsorbable disaccharide lactulose, which has been used to treat HE since 1966. The putative mechanisms of action are multiple. The cathartic effect due to the osmolar load is thought to reduce time allowed for NH_3 absorption as well as to increase fecal nitrogen excretion. Lactulose catabolism generates

TABLE 124.4 Ammonia-Reducing Pharmacologic Therapies

Agent	Dose
Lactulose	15-45 mL orally 2-4 times a day
Sodium benzoate	5 mg orally twice a day
Rifaximin	400 mg orally 3 times a day

lactic acid, thereby acidifying colonic contents, which causes protonation of NH_3 into ammonium (NH_4^+), which is poorly absorbed, remains trapped in the lumen, and is excreted. Finally, lactulose inhibits glutaminase activity and interferes with the intestinal uptake of glutamine and its subsequent metabolism to NH_3. Lactulose is titrated to achieve two to three bowel movements per day, with a starting dose of 30 mL (20 g of lactulose) twice daily. It has been evaluated against placebo in numerous randomized controlled trials (RCTs). A recent meta-analysis concluded that lactulose is beneficial in treating both MHE and OHE. It reduces overall mortality when used for HE prevention as well as for OHE and is associated with a reduction in the risk of developing serious liver-related complications including liver failure, variceal hemorrhage, severe infections, spontaneous bacterial peritonitis, and hepatorenal syndrome. It is associated with only nonserious and mostly transient adverse events, is readily available, and inexpensive. As such, it represents the first-choice treatment for the secondary prophylaxis of OHE LEVEL 1.[1]

The other evidence-based approach is through modulation of fecal flora with rifaximin 550 mg orally 3 times a day for 14 days. Rifaximin is a minimally absorbed antibiotic with broad-spectrum activity against gram-positive, gram-negative, and anaerobic bacteria. Its site of action is the small bowel, where it lowers the bacterial load up to 1,000-fold. Trials and meta-analyses demonstrated a beneficial effect on recovery from HE, on secondary prevention of HE, and on mortality. It is usually given in addition to lactulose. LEVEL 1.[1]

Many other interventions have been studied but the evidence remains less robust, and their use is limited to use as a supplement to lactulose and rifaximin in refractory cases. They include NH_3-lowering agents such as sodium benzoate, which lowers NH_3 levels by combining with glycine to form hippurate, thereby allowing renal excretion, or the purgative laxative polyethylene glycol as well as L-ornithine L-aspartate and oral branched-chain amino acids. In the face of medically resistant HE, patients should be investigated for large portosystemic shunts because these can be treated by embolization therapy. In the presence of a TIPS, reducing caliber of the TIPS can lead to clinical improvement and should be considered in patients with severe post-TIPS HE. Liver transplantation is the only definitive treatment option.

General care measures include appropriate hydration and nutritional support with protein intake of 1.2 to 1.5 g/kg/d and correction of electrolyte abnormalities. Treatment of chronic hyponatremia must be performed carefully because cirrhotic patients are at higher risk for osmotic demyelination syndrome. Correction of hyponatremia should be performed no more quickly than 12 mmol/L per 24 hours. Correction of hypokalemia is also an essential component of therapy because it increases renal NH_3 production. After a first episode of OHE, secondary prophylaxis is recommended with lactulose and rifaximin to prevent recurrence. This therapy should be continued indefinitely.

Outcome

Even without obvious clinical manifestations, MHE patients do not fare well. After diagnosis, 50% of patients will be hospitalized within a year and 75% will die within the next 4 years. The future is even grimmer after a first episode of OHE: 40% will have a recurrent episode by the end of the year. The cumulative survival at 1 year is 42%, and, at 3 years, it is a mere 23%.

ACUTE LIVER FAILURE AND CEREBRAL EDEMA

Epidemiology

ALF is rare in developed countries, with an incidence ranging from 1 to 8 cases per million per year. There are approximately 2,000 cases annually in the United States. It is seen most commonly in previously healthy adults in their 30s, and the most prominent cause is drug-induced liver injury dominated by acetaminophen-induced hepatotoxicity (Fig. 124.2). It is of interest to the neurologist to know that other causes of ALF include carbamazepine, phenytoin, and valproic acid.

Pathobiology

Multiple Organ Failure

ALF results in a shutdown of its synthetic, metabolic, detoxification, and immunologic functions. Loss of coagulation factor synthesis leads to coagulopathy, and necrotic hepatocytes trigger an intense systemic inflammatory syndrome. This inflammatory state produces vasoparesis and is often complicated by acute renal failure and acute lung injury. Loss of neoglucogenesis may lead to hypoglycemia and reduced lactate clearance. Immunoparesis puts patients at high risk for sepsis, and bone marrow suppression manifests as cytopenia.

Encephalopathy and Cerebral Edema

The etiology of cerebral edema in ALF is not fully understood and is probably multifactorial, combining cytotoxic brain edema due to the astrocytic accumulation of glutamine and vasogenic edema characterized by increases in cerebral blood volume and cerebral blood flow [CBF], combined with disruption of the BBB.

Acute NH_3 accumulation produces different neurologic consequences than the chronic hyperammonemia seen in cirrhotic patients. The rapid transformation of NH_3 to glutamine inside the astrocytes does not allow for compensatory mechanisms such as the release of taurine or myoinositol. The osmotic effect causes astrocytes to take in water and swell, creating cytotoxic brain edema. This is why arterial NH_3 levels in ALF are highly correlated with prognosis and the extent of cerebral edema.

FIGURE 124.2 Common causes of acute liver failure in the United States. Abbreviations: HAV, hepatitis A virus; HBV, hepatitis B virus.

Patients with NH_3 levels less than 75 μmol/L usually do not develop encephalopathy at all, and those with NH_3 greater than 200 μmol/L have a 55% risk of developing cerebral edema with concomitant intracranial hypertension. The rapid buildup of glutamine is partially transformed to glutamate, which may explain the aggressive and agitated delirium seen in some patients and their propensity for seizures.

Numerous other causal pathways have been invoked to explain why vasogenic cerebral edema occurs with ALF. The most consistent finding implicates a variety of inflammatory mediators, including interleukin 1β, tumor necrosis factor α, interleukin 6, which are released as part of the systemic inflammatory response syndrome, triggered by acute hepatic necrosis. Excessive levels of nitric oxide, a vasodilator, have also been invoked. The result is loss of normal autoregulation, leading to vasodilation and hyperemia, and BBB disruption, leading to fluid extravasation into the brain. The vasogenic component of brain edema tends to occur prior to the onset of herniation due to global cerebral edema.

Clinical Features

The clinical picture of ALF is dominated by acute hepatic dysfunction, unregulated systemic inflammation with multiorgan dysfunction, and cerebral edema with intracranial hypertension, which is the most feared complication (Fig. 124.3).

The characteristic sleepiness and asterixis of cirrhotic patients are not reliable indicators of early encephalopathy in ALF. Instead, forewarning signs of impending cerebral edema are usually the onset of aggressive behavior and agitated delirium associated with hyperreflexia and ankle clonus. Mental status changes can quickly follow with the patient lapsing into coma in just a few hours. Hypoglycemia must be ruled out as a cause, especially with acetaminophen toxicity where it is highly prevalent (up to 55%). Multifocal myoclonus and excessive startle response are well described and later stages may reveal spasticity and extensor posturing as well extensor plantar responses. Pupillary responses are impaired only when intracranial pressure (ICP) is frankly elevated and brain herniation has occurred. Oculomotor dysfunction is uncommon, but dysconjugate gaze and periodic alternating gaze deviation are reported. The finding of systolic blood elevation and bradycardia (otherwise known as the *Cushing syndrome*) is late and unreliable. Seizures, albeit generally nonconvulsive, are also a frequent occurrence in ALF. Up to 30% of patients monitored with continuous electroencephalogram have evidence of electrographic seizures.

Diagnosis

ALF is defined as the onset of coagulopathy (INR >1.5) and encephalopathy (any degree of altered mentation) secondary to acute liver injury in a patient without preexisting liver disease. The time from the start of illness to encephalopathy is variable from hyperacute (less than a week) to subacute (up to 26 wk). Patients with Wilson disease, vertically transmitted hepatitis B virus, or autoimmune hepatitis may be included if the disease has only been recognized for less than 6 months.

When ALF is suspected, the history must be very thorough, with a focus on drug and medication ingestion, including over-the-counter medications or supplements, as well a possible viral exposure, including travel history. Although the cause of ALF remains unknown in close to 20% of cases, it is the single most important prognostic factor and might call for specific treatment, so it must be sought aggressively. In addition to laboratory testing and imaging, serial biochemical testing should be performed, including NH_3, glucose, and lactate levels; liver and renal function; electrolytes; and coagulation panels.

Treatment

General Management

Patients with a diagnosis of ALF must be hospitalized, and those developing encephalopathy should be transferred to a critical care unit because they can deteriorate in a matter of hours. Frequent neurologic assessments are mandatory in ALF patients. Special attention should be dedicated to development of delirium, mental status changes, abnormal motor tone and deep tendon reflexes, and myoclonus. Those progressing to West Haven stage III or IV (see Table 124.1), which usually corresponds to a

FIGURE 124.3 Multiorgan dysfunctions associated with acute liver failure. Abbreviation: ARDS, acute respiratory distress syndrome.

TABLE 124.5 Acute Liver Failure Etiologies and Specific Treatments

Etiology	Specific Treatment
Acetaminophen poisoning	IV NAC[a]
Drug-induced liver injury (non-acetaminophen)	IV NAC[a]
Mushroom poisoning (*Amanita phalloides*)	Penicillin G (1 million U/kg/d) and IV NAC[a]
HBV	Lamivudine
Herpesvirus or varicella-zoster virus	Acyclovir (10 mg/kg IV every 8 h)
Autoimmune	Prednisone (40-60 mg/d)
ALF of pregnancy or HELLP	Delivery

Abbreviations: ALF, acute liver failure; HBV, hepatitis B virus; HELLP, hemolysis, elevated liver enzymes, low platelets; IV, intravenous; NAC, *N*-acetylcysteine.

[a]Loading dose is 150 mg/kg in 5% dextrose over 15 minutes; maintenance dose is 50 mg/kg given over 4 hours followed by 100 mg/kg administered over 16 hours (or 6 mg/kg/h).

Glasgow Coma Scale score of 8 and less (see **Table 19.2**), should be intubated and strong consideration should be given to invasive ICP monitoring. Communication with a transplant center is essential and transfer criteria have to be determined very early in the evaluation process. Depending on the etiology of ALF, specific treatment should be instituted promptly, especially in the case of acetaminophen poisoning (**Table 124.5**). Hypoglycemia and hyponatremia are common, can exacerbate the severity of the neurologic insult, and must be carefully prevented.

High-Volume Plasma Exchange

Therapeutic plasma exchange (TPE) is a procedure in which a large volume of plasma is removed from a patient, through a centrifugation process, which is then replaced with 5% albumin and physiologic saline or plasma. The bulk removal and replacement of plasma removes pathologic substances and cytokines, resulting in attenuation of innate immune activation and an amelioration of multi-organ dysfunction. A recent randomized clinical trial demonstrated improvement in clinical and paraclinical variables, most importantly an increase in liver transplant-free survival in patients with ALF treated with TPE. All etiologies were included, associated with at least grade 2 HE having developed in the last 24 hours. Patient plasma was removed at a rate of 1 to 2 L/h with replacement with fresh frozen plasma in equivalent volume for a total of 15% of ideal body weight of volume exchange. TPE is now recommended in patients meeting the abovementioned inclusion criteria LEVEL 2.[2,3]

Intracranial Pressure and Transcranial Doppler Monitoring

Patients with grade III encephalopathy (see **Table 124.1**) have a risk of experiencing elevated ICP of 30%, whereas in grade IV patients, it climbs to 70%. Noncontrast head computed tomography (CT) is often performed to rule out other concomitant pathologies, such as bleeding, but the usual finding that implies a high risk of intracranial hypertension is global cerebral edema with convexity sulcal effacement, effacement of the basal cisterns and ventricles, and loss of gray-white matter differentiation.

Transcranial Doppler (TCD) is a noninvasive technique allowing indirect evaluation of both CBF and ICP (see Chapter 24). In ALF, because global cerebral edema is primarily vasogenic and caused by hyperemia and vasodilation, the rise in ICP is usually preceded by an increase in CBF and hence in TCD flow velocities. Early on, TCD flow velocities are elevated above normal values (60 cm/s in a healthy young person), and the pulsatility index (peak systolic minus diastolic flow velocity divided by mean flow velocity) is reduced below the normal value of 1.0 due to downstream vasodilation. Brain injury is highly reversible at this stage, and for this reason, the triad of coma, global cerebral edema on CT, and elevated flow velocities on TCD is the ideal time for an ICP monitor to be inserted.

After ICP has been massively elevated for a sustained period of time, the brain remains engorged but hypoperfused, CBF falls, metabolic changes in the brain cause cellular swelling, and cytotoxic brain edema ensues. At this late stage, TCD evolves toward a picture consistent with brain death: Mean flow velocities drop, the pulsatility index increases, and eventually, readings evolve to isolated systolic flow velocity spikes with diastolic flow arrest diagnostic of brain death (see Chapter 20).

As for other neurocritical care patients, invasive ICP monitoring (see Chapter 34) is the gold standard for monitoring when intracranial hypertension is the main threat to life. Although its use in ALF is still contentious, it is now recommended in patients with high-grade encephalopathy awaiting transplantation in centers with appropriate expertise. Associated with encephalopathy, the following factors are considered indications for placement of an ICP monitor.

- Global cerebral edema on CT
- Arterial NH_3 greater than 150 mmol/L
- Age younger than 50 years
- TCD indices of high CBF
- Concurrent renal or cardiovascular organ failure

The main concern of placing an invasive ICP monitor is bleeding because most patients with ALF are coagulopathic. Recent series report clinically significant bleeding in ALF patients after standard reversal procedures at the same order of magnitude as for other intracranial pathologies. Reversal of coagulopathy when placing an intracranial monitoring device should be taken seriously. Off-label usage of recombinant factor VIIa (40 μg/kg given 30 min before the procedure) is used at many liver transplant centers throughout the world to correct the coagulopathy prior to ICP monitor placement. Recombinant factor VIIa has been associated with a 5% risk of thrombotic complications, including brain and myocardial infarction.

We also recommend keeping platelets over 50,000 and to correct hypofibrinogenemia (fibrinogen <100 mg/dL) with cryoprecipitate prior to insertion. Elevated prothrombin time/INR can also be corrected with fresh frozen plasma (15 mL/kg).

Intracranial Pressure Management

Standard ICP management principles (see Chapter 111) apply to ALF patients but with some particularities. Hypertonic saline (3%) given prophylactically (at a rate of 0.5 mL/kg/h) with a sodium target of 145 to 155 mEq/L has been shown to reduce the incidence and severity of ICP crisis. Prophylactic induction of hypernatremia is thus recommended LEVEL 2[3] in high-risk patients (encephalopathy grade III or IV, NH_3 >150 μmol/L, acute renal failure or requiring vasopressors). In the event of a herniation event, mannitol boluses (20% solution at a dose of

0.5-1 g/kg) are successful in resolving ICP crisis in ALF patients and improve survival compared to placebo. Corticosteroids are not of value in cerebral edema caused by ALF and are probably harmful and should not be used LEVEL 1.[3]

The role of therapeutic hypothermia is debated. Case series show great improvement in ICP control and impressive survival rates, but an RCT and retrospective cohort studies have failed to show better outcomes with cooling, albeit showing no higher rates of bleeding or infection. Induction of hypothermia to 33°C may be considered as a rescue intervention in patients with refractory ICP crisis, refractory to sedation and paralysis, bolus osmotherapy, and hyperventilation as a bridge to liver transplantation. Indomethacin (25 mg intravenously) has been shown in a few ALF patients with ICP refractory to mannitol to dramatically reduce ICP without documented adverse effects.

Seizures

With a reported frequency of nonconvulsive seizures in up to 30% of patients, grade III or IV encephalopathy should be monitored with continuous electroencephalogram for a minimum of 48 hours. Prophylactic phenytoin failed to improve outcomes in one RCT and is thus not recommended.

Ammonia Clearance

Therapies used for HE, such as lactulose, have not been proven useful in acutely reducing blood level of NH_3 in ALF patients. Some clinical data show that hemofiltration with continuous renal replacement therapy (CRRT) might be the best way to control arterial NH_3 levels, but more convincing results have been seen with high-volume plasma exchange LEVEL 1.[2] Clearance is closely correlated with ultrafiltration rate up to 90 mL/kg/h, and glutamine is also likely to be cleared in the process. CRRT also allows for tighter control of serum sodium levels, intravascular volume, pH, and temperature.

Artificial Liver Support Systems

Numerous extracorporeal liver support systems have been developed; currently, the only U.S. Food and Drug Administration–approved device is the Molecular Adsorbent Recirculating System. This nonbiologic artificial liver support system is based on a dialysis technique using an albumin-coated membrane. It allows detoxification by removal of not only water-soluble toxins but also, in contrast to CRRT, albumin-bound substances. Among proven benefits in ALF patients, there is improvement in hemodynamic stability, reduction in ICP, and improvement of HE. The only large RCT did not show a survival benefit, although it was highly underpowered. At present, Molecular Adsorbent Recirculating System should only be considered as a "bridge to transplant" or in the context of a randomized trial.

Transplantation

Orthotopic liver transplantation is the only definitive therapy for those whose liver function does not recover. Given the usually rapid evolution toward cerebral edema, candidacy must be assessed promptly. Numerous prognostic scores have been developed trying to predict who has a poor prognosis with medical management alone and hence who will benefit most from emergent liver transplantation. None of them is universally accepted, but the most widely used are the King's College Criteria (Table 124.6). Adult patients with sudden acute- and severe-onset ALF according to the King's College Criteria have a life expectancy less than 7 days without transplant and are granted 1A status, making them the highest priority, but up to 25% will die while on the waiting list. As of 2019, more than 13,000 patients were on the liver transplant waiting list in the United States with about 10% of livers usually allocated to ALF patients.

TABLE 124.6 King's College Criteria for Acute Liver Failure

Acetaminophen-Induced ALF	
Strongly consider OLT listing.	• Arterial lactate >3.5 mmol/L after early fluid resuscitation
List for OLT.	• pH <7.3 *or* • Arterial lactate >3.0 mmol/L after adequate fluid resuscitation
List for OLT if all three occur within a 24-h period.	• Presence of grade 3 or 4 hepatic encephalopathy • INR >6.5 • Creatinine >3.4 mg/dL
Non–Acetaminophen-Induced ALF	
List for OLT.	• INR >6.5 *and* • Encephalopathy present (irrespective of grade)
List for OLT if any three of the following (and any grade of encephalopathy present).	• Age younger than 10 y or older than 40 y • Jaundice for >7 d before development of encephalopathy • INR ≥3.5 • Serum bilirubin ≥17 mg/dL • Unfavorable etiology, such as Wilson disease, idiosyncratic drug reaction, seronegative hepatitis

Abbreviations: ALF, acute liver failure; INR, international normalized ratio; OLT, orthotopic liver transplantation.

Outcome

With optimization of medical management and improved organ allocation system, the overall mortality of ALF is now between 30% and 40%. The etiology of ALF is one of the most important predictors of outcome. For example, transplant-free survival is largely over 50% for acetaminophen poisoning, hepatitis A, or pregnancy-related disease. On the contrary, survival without transplantation is less than 25% in Wilson disease, Budd-Chiari syndrome, or autoimmune hepatitis. With emergent transplantation, although the survival at 1 year is less than for elective transplantation (mainly due to infection in the first 3 months), ALF patients have a better long-term survival.

125 Renal Disease, Electrolyte Disorders, and the Nervous System

J. Kirk Roberts and Stephan A. Mayer

KEY POINTS

1. Neurologic disease in patients with renal failure may be related directly to the renal failure or may be related to an underlying condition that damages both the kidneys and the nervous system.
2. Many neurologic complications of renal failure have become less common due to earlier and more aggressive dialysis and renal transplantation. However, this has led to an increase in neurologic complications of immune suppression.
3. Sodium homeostasis is under the control of the brain and the kidneys. Hyponatremia is a common condition encountered in the neurologic intensive care unit and is most commonly related to volume depletion, the syndrome of inappropriate antidiuretic hormone secretion, and cerebral salt wasting.

INTRODUCTION

Renal disease is most commonly associated with neurologic disease when both are related to an underlying condition (eg, diabetes mellitus, hypertension) that damages both systems. However, renal disease and resultant azotemia (blood urea nitrogen elevation or uremia) can injure both the central nervous system (CNS) and the peripheral nervous system. With the increase in aggressive kidney dialysis and transplantation, the incidence of many neurologic conditions associated with chronic renal failure has declined, but a new constellation of neurologic complications associated with dialysis and transplantation has become more important.

UREMIC ENCEPHALOPATHY

The differential diagnosis of encephalopathy in a patient with renal failure is wide and includes metabolic, infectious, structural, and other causes. Fluid and electrolyte disturbances are common. Drugs that are excreted in the urine may accumulate and dosing must be adjusted.

Pathobiology

Uremia itself can cause encephalopathy. The symptoms of *uremic encephalopathy* are usually more severe in patients with more severe azotemia; they are often evident earlier and more severely in patients with acute as opposed to chronic renal failure. The specific factors that cause encephalopathy are still not identified. The earliest indicator is sensorial clouding, which progresses to delirium, obtundation, and even coma. In addition to cognitive changes, patients exhibit weakness uncoordination and are unsteady. Focal symptoms or signs may wrongly suggest a focal process. Asterixis is commonly seen, with jerking movements arising from lapses of posture holding, as of the outstretched hands. Multifocal myoclonus, involuntary twitches occurring randomly throughout the body, may become apparent, usually after stupor or coma has supervened. Tetany may be overt, with spontaneous carpopedal spasm, painful muscle contractions in hands and feet, or latent as manifest by a Trousseau sign (sustained muscle contraction and cupping of the hand, induced by arterial occlusion). Seizures are a late manifestation of uremic encephalopathy. Fluctuation of clinical symptoms and signs from day to day is characteristic.

Diagnosis

No laboratory value, including specific evaluations of renal function, correlates well with clinical symptoms and signs of uremia. Lumbar puncture may reveal elevated cerebrospinal fluid (CSF) protein, sometimes exceeding 100 mg/dL, and occasionally a mild pleocytosis but is primarily performed to exclude an infectious cause of encephalopathy. Computed tomography or magnetic resonance imaging (MRI) findings are usually nonspecific but may help to exclude ischemic stroke, intracerebral hemorrhage, subdural hematoma, or hydrocephalus. Electroencephalogram, like the clinical state, is usually more strikingly abnormal in acute renal failure than in chronic renal failure. The background activity is slow with theta and delta waves more prominent in the frontal regions. Triphasic waves may appear. Nonconvulsive status epilepticus is an important treatable cause of encephalopathy that can be identified only by electroencephalogram with dramatic improvement when appropriately managed.

Treatment

Uremic encephalopathy usually responds very well to dialysis, suggesting that one or more dialyzable substances are responsible. Sometimes, response is delayed for 1 to 2 days. A variety of metabolites acting toxically when accumulating have been postulated as the etiology of uremic encephalopathy, but no single substance has been identified as the sole or major cause. Hormonal changes, electrolyte abnormalities, altered calcium homeostasis, and imbalance of excitatory and inhibitory neurotransmission are all thought to play a role.

DIALYSIS DISEQUILIBRIUM SYNDROME

Dialysis disequilibrium syndrome describes a condition in which a variety of neurologic symptoms manifest most often, with rapid correction of uremia at the start of a dialysis program. It is

more common in those with more severe azotemia. Symptoms vary from mild headache, nausea, and muscle cramps to, rarely, delirium, obtundation, and convulsions. The syndrome is usually self-limited, subsiding in hours, but delirium may persist for several days. Although the pathogenesis is controversial, shift of water into brain is probably the cause of syndrome. The rapid reduction in blood osmoles cannot be paralleled as rapidly by a reduction in brain osmoles, resulting in an osmotic gradient between blood and brain, causing movement of water into brain and cerebral edema and encephalopathy. With improvements in dialysis, this syndrome is much less frequent now. Gradual initiation of dialysis may help prevent. Before diagnosing dialysis disequilibrium, other causes of cerebral symptoms should be excluded, including uremia, other metabolic disturbances, infection, posterior reversible encephalopathy syndrome, and others. Treatment of patients who develop dialysis disequilibrium syndrome can usually be managed by adjusting sodium in the dialysate to avoid osmotic shifts and in those with persistent or severe symptoms; mannitol or hypertonic saline can similarly be used.

DIALYSIS DEMENTIA

A subacute, progressive, usually fatal encephalopathy rarely occurs in patients who are chronically dialyzed. The first symptom is usually a stammering, hesitancy of speech and, at times, speech arrest. The speech disorder is intensified during and immediately after dialysis and at first may be seen only during these periods. As the disorder progresses, speech becomes more dysarthric and aphasic along with personality change, psychosis, myoclonus, seizures, and occasionally focal neurologic abnormalities. Brain imaging and CSF findings are usually unremarkable and, again, are most helpful in excluding other causes of encephalopathy. Increased dialysis time and renal transplantation do not seem to alter the course of the disease. Many dialysis patients are older and suffer from vascular diseases, and common causes of dementia such as Alzheimer disease and vascular dementia must be considered. However, historically, aluminum toxicity was a unique cause of dementia in those with renal disease and treated with hemodialysis. Evidence suggesting this link included the finding that aluminum content was consistently elevated in the cerebral gray matter of patients who died from this condition, and municipal water supplies heavily contaminated with aluminum were linked to the syndrome in epidemiologic studies. The frequency of the disease markedly diminished when aluminum was removed from the water used during dialysis and the use of aluminum-containing phosphate binders and antacids was reduced.

CEREBROVASCULAR DISEASE

Stroke is prevalent in patients with renal failure, mostly because of shared risk factors. However, renal failure may additionally promote atherogenesis through several mechanisms. Hypotension during dialysis may result in watershed infarction. Renal failure is associated with platelet dysfunction, and anticoagulants used during hemodialysis may contribute to intracerebral hemorrhage or subdural hematoma. Chronic subdural hematoma may present with an encephalopathic picture without focal motor or sensory symptoms and signs. Autosomal dominant polycystic kidney disease is associated with an increased risk of saccular aneurysm and subarachnoid hemorrhage (SAH).

RESTLESS LEGS SYNDROME

At least 20% of patients with chronic renal failure suffer from creeping, crawling, prickling, and pruritic sensations deep within the legs particularly when at rest and improving with movement (see Chapter 78). Periodic limb movements of sleep, an involuntary repetitive jerking of the legs while asleep, may coexist. Dialysis often does not lead to significant improvement, and treatment is similar to that in patients without renal failure.

PERIPHERAL NEUROPATHY

The most common neurologic consequence of chronic renal failure is a distal, symmetric, predominantly axonal, mixed sensorimotor neuropathy affecting the legs more than the arms. Cranial nerves, particularly vision and hearing, and the autonomic nervous system may be affected. The rate of progression, severity, prominence of motor or sensory symptoms and signs, and degree of pain varies. Decreased vibratory and temperature sense in the feet are the earliest signs, and sensory symptoms and signs usually predate motor. In general, the neuropathy evolves over several months but may be fulminant.

Pathobiology

Pathologically, uremic neuropathy is usually a primary axonal degeneration with secondary segmental demyelination; there is also a predominantly demyelinating type. Because uremic neuropathy improves with hemodialysis, it seems likely that the neuropathy results from the accumulation of dialyzable metabolites. The control of neuropathy in some patients depends on increased hours of dialysis each week. The use of erythropoietin has also been reported to improve uremic neuropathy.

Diagnosis

Other causes must always be considered given the coexistence of renal diseases and conditions that predispose to peripheral neuropathy (eg, diabetes mellitus, amyloidosis). Mononeuropathies, such as carpal tunnel syndrome caused by damage to the median nerve at the wrist or ulnar neuropathy, may occur, perhaps owing to an increased susceptibility of at-risk nerves to injury or as a vascular steal phenomenon after arteriovenous fistula. Electrophysiologic studies are often abnormal, even in those with no symptoms, with both decreased amplitudes and slowing. Among most patients who enter chronic dialysis programs, the neuropathy stabilizes or improves slowly. Patients with mild neuropathy often recover completely, but those who begin dialysis with severe neuropathy rarely recover even after several years, and some may continue to progress. However, lack of improvement or progression of symptoms while on dialysis should suggest an evaluation for an alternative diagnosis.

Management

Both dialysis and renal transplantation often have a significant beneficial effect on uremic neuropathy, with transplantation thought to be more effective. Motor nerve conduction velocities can increase within days of transplantation along with continued

improvement for several months, sometimes with complete recovery, unless there was severe axonal degeneration before transplantation.

The symptomatic treatment of painful uremic neuropathy is similar to the treatment of any painful peripheral neuropathy (see Chapter 91) but with careful attention to medication dosing, given the presence of renal failure.

MYOPATHY

In patients with renal failure, myopathy with proximal limb weakness, fatigability, and atrophy is a poorly understood condition. Muscle enzymes and electromyogram are usually normal. Muscle biopsy may reveal nonspecific alterations and sometimes type II fiber atrophy. Electrolyte abnormalities, in particular potassium, calcium, and magnesium, must be considered. If the patient has been treated with a kidney transplant and is taking steroids, a steroid myopathy may be considered.

NEUROLOGIC COMPLICATIONS OF RENAL TRANSPLANTATION

Renal transplantation is the preferred treatment of end-stage renal disease, and with advances in transplantation medicine, these patients live longer and are more at risk for the adverse consequences of long-term immunosuppression.

A femoral neuropathy may complicate renal transplant surgery caused by perioperative compression or traction. It can usually be managed with physical therapy and time. Occasionally, a compressing hematoma may need to be evacuated or nerve repair may be needed for a more severe direct nerve injury.

Transplant patients suffering systemic features of rejection may also present with encephalopathic symptoms including confusion and even seizures. Symptoms usually begin within a few months of transplant, but some occur later. Treatment of rejection usually leads to improvement.

Posterior Reversible Encephalopathy Syndrome

Several drugs are used to prevent transplant rejection, and each has adverse effects. Of particular interest to the neurologist is the *posterior reversible encephalopathy syndrome* usually seen in those patients treated with cyclosporine or tacrolimus (see Chapter 44). Posterior reversible encephalopathy syndrome may also be seen in nontransplanted patients with renal disease and hypertension. Symptoms include headache, visual disturbance, encephalopathy, and seizures. Blood pressure is usually elevated. MRI reveals changes in the white matter, most extensive in the occipital and parietal regions, that suggest vasogenic edema. Treatment involves lowering blood pressure and, whenever possible, discontinuing immunosuppressive agents. Obviously, patients with transplanted organs require immunosuppression; if medications are substituted, the patient will need continued monitoring for PRES. Patients with seizures should be treated with anticonvulsants. Late recurrence of seizures after successful treatment is low, and the anticonvulsant can usually be discontinued in the uncomplicated patient once symptoms and imaging have resolved, although some advocate continuing for 1 to 3 months.

Primary Central Nervous System Lymphoma

The risk that a lymphoma will develop after a transplant is about 35 times more than in normal people; the increased risk depends almost entirely on the increased incidence of primary CNS lymphoma. These are almost always B-cell lymphomas developing from immunosuppression-related Epstein-Barr virus infection causing lymphocyte proliferation. The tumor typically appears between 5 and 45 months after transplantation. The resulting clinical syndromes include increased intracranial pressure, rapidly evolving focal neurologic signs, or combinations of these. Convulsions are rare. The lymphoma may be multicentric and may involve the meninges. Treatment may include immunosuppression withdrawal, chemotherapy, and radiation.

Opportunistic Infections

Infections occur often in transplant patients, and a high index of suspicion must be maintained because the usual inflammatory response may be impaired diminishing the severity of symptoms. New headache or mental changes should lead the clinician to consider brain imaging and lumbar puncture. Viral infections with cytomegalovirus, herpes zoster virus, varicella-zoster virus, human herpes virus 6, Epstein-Barr virus, and John Cunningham virus can often be diagnosed on CSF with culture or polymerase chain reaction. Bacterial and tuberculous meningitis are also considerations. Systemic fungal infections are common, and secondary brain abscess formation may occur. In almost all cases, the primary source of infection is in the lung. Chest radiographs and the presence of fever aid in differentiating fungal brain abscess from brain tumor in recipients of transplants. *Aspergillus* has a unique predilection for dissemination to brain and accounts for most fungal brain abscesses; *Candida*, *Nocardia*, and *Histoplasma* are found in the others. The clinical syndrome resulting from these infections is usually delirium accompanied by seizures. Headache, stiff neck, and focal signs also occur but not commonly. The CSF is often remarkably bland, and brain biopsy may be the only reliable way to establish a diagnosis. The distinction of fungal brain abscess from possibly radiosensitive brain tumor makes it important to consider this procedure.

HYPONATREMIA

Sodium and fluid homeostasis is under the control of the brain and kidneys. The neurologist, particularly in the neurologic intensive care unit, is frequently confronted by hyponatremia (serum sodium <135 mEq/L). In this setting, the most common causes of hyponatremia are volume depletion, the syndrome of inappropriate antidiuretic hormone secretion (SIADH), and cerebral salt wasting (CSW).

Clinical Features

Hyponatremia can not only be caused by brain injury but can also further impair neurologic function and cause a vast array of clinical manifestations, ranging from mild confusion to death. The severity of symptomatology is primarily related to the speed of sodium reduction, rather than the absolute sodium level itself. Sodium is the principle osmotically active solute in

the extracellular fluid compartment. If the sodium concentration falls quickly (>1 mEq/h), free water moves into the intracellular compartment, leading to cellular swelling and edema. Unlike other organs, the CNS tolerates this process extremely poorly. Acute hyponatremia can lead to global cerebral edema and severe clinical manifestations, including seizures, coma, or death from brainstem herniation.

When sodium levels drop gradually, cells compensate by reducing the intrinsic osmolality of the intracellular compartment. This process, which involves release of intracellular electrolytes such as potassium and elimination of organic osmolytes, takes hours to days. As a result, normal cellular volume is maintained in chronic hyponatremia, but subtle neurologic dysfunction in the form of neurocognitive dysfunction, impaired reaction times, and gait instability results from these intrinsic changes in neuronal intracellular composition. Hospitalized patients with chronic hyponatremia have an increased risk of mortality and a two- to fourfold increased fall risk compared to normonatremic patients.

Diagnosis

The medical history is an important first step in the evaluation of hyponatremia and in particular includes information about fluid loss (or excess intake), low protein intake, medications, history of heart failure, cirrhosis, kidney failure, hypothyroidism, adrenal insufficiency, lung cancer, and, of course, CNS disease.

In addition to the history, physical examination should start with an assessment of *volume status* by evaluating blood pressure and heart rate, skin turgor, the mucous membranes, and jugular venous pressure. Measurement of fluid inputs and outputs typically demonstrate positive net fluid balance in patients who are hypovolemic, as the kidneys appropriately retain fluid to correct the problem. A spot urine sodium concentration is typically low in hypovolemic states (<25 mEq/L), representing avid renal sodium retention. A low central venous pressure is fairly specific for hypovolemia; otherwise, central venous pressure is a poor indicator of volume status. Advanced diagnostic methods in the intensive care unit for evaluating volume status include use of bedside ultrasound to diagnose collapsibility of the inferior vena cava with spontaneous respirations and cardiac output monitors that can measure the global end-diastolic volume index of the heart.

Essential laboratory testing in hyponatremia includes serum osmolality, urine osmolality, and urine electrolytes, in addition to standard serum chemistries. If serum osmolality is low, then true hypotonic hyponatremia is confirmed (Fig. 125.1). If serum

FIGURE 125.1 Diagnostic algorithm for identifying the cause of hyponatremia. Step 1 is to confirm the presence of hypotonic hyponatremia by checking serum osmolality. Step 2 is to evaluate volume status. Euvolemic hyponatremia is usually due to syndrome of inappropriate antidiuretic hormone secretion. Hypovolemia hyponatremia may be due to extrarenal sodium losses such as vomiting or diarrhea, or inappropriate renal losses, as occurs with cerebral salt wasting.

TABLE 125.1 Syndrome of Inappropriate Antidiuretic Hormone Secretion Versus Cerebral Salt Wasting

	SIADH	CSW
Serum sodium (mEq/L)	<135	<135
Serum osmolality (mOsm/kg)	<275	<275
Urine osmolality (mOsm/kg)	>100 (usually >300)	>100 (usually >300)
Urine sodium (mEq/L)	>40	>40
Volume status	Euvolemic to hypervolemic	Hypovolemic
Response to isotonic saline	No effect	Improved hyponatremia

Abbreviations: CSW, cerebral salt wasting; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

sodium is low but serum osmolality is normal, elevated lipids or proteins may account for a measured pseudohyponatremia. If sodium is low and osmolality is elevated, then another substance is contributing to osmoles such as glucose, urea, alcohol, or mannitol.

When hypotonic hyponatremia is confirmed, classification of volume status as hypovolemic, euvolemic, or hypervolemic is key for identifying the cause (see **Fig. 125.1**). Analysis of urine sodium is a key ancillary test. Calculation of the fractional excretion of sodium (**Table 125.1**) is less than 1% in patients who are hypovolemic or have reduced effective circulating blood volume and normal renal function, reflecting a corrective pattern of avid sodium retention. An important exception is when fluid losses and hypovolemia are caused by excessive and inappropriate sodium excretion, as occurs with untreated CSW (**Table 125.2**).

In this setting of SIADH, patients are euvolemic, spot urine sodium is greater than 40 mEq/L, and the fractional excretion of sodium is greater than 1%. Because antidiuretic hormone (ADH) is inappropriately elevated, urine osmolality is more than a maximally dilute urine of 100 mOsm/kg and usually more than 300 mOsm/kg.

An SIADH from enhanced ADH release may occur in the setting of almost any CNS disease, including stroke, trauma, brain tumor, or encephalitis, and with acute peripheral neuropathies such as Guillain-Barré syndrome.

CSW is typically encountered in patients with SAH but can occur with other forms of acute CNS injury as well. In this condition, sympathetic nervous system activation release of circulating factors such as brain natriuretic factor drive excessive sodium excretion while suppressing the normal renin-angiotensin system response to hypovolemia. A CSW as a cause of hyponatremia is about one-tenth as common as SIADH. In some cases, most often SAH, hyponatremia can be the result of dual physiologic processes that favor the combination of excessive sodium losses and inappropriate ADH elevation.

Management

Acute Symptomatic Hyponatremia

Treatment of hyponatremia in neurologic patients, whether acute or chronic, is important. Symptomatic acute hyponatremia leading to brain edema is a medical emergency and should be treated with hypertonic saline. The mainstay of therapy is a 3% sodium chloride–acetate solution, infused at a rate of 0.25 to 1.0 mL/kg/h, depending on the severity of symptoms and sodium level. Serum sodium level should be monitored every 4 hours, with the rate of the infusion adjusted to attain a rate of correction of no more than 12 mEq/L over 24 hours (0.5 mEq/L/h). More rapid aggressive correction of hyponatremia must be avoided because of the possibility of osmotic demyelination or central pontine myelinolysis (CPM).

Chronic Hyponatremia

The mainstay of treating *hypovolemic hyponatremia*, whatever the cause, is isotonic fluid resuscitation in the form of normal (0.9%) saline. In most cases, correction of the volume deficit results in normalization of the sodium concentration.

The conventional first-line treatment for SIADH commonly involves fluid restriction, but this should more correctly be termed *free water restriction*. All sources of free water, whether oral or in the form of hypotonic intravenous fluids or enteral feeds, should be restricted in SIADH, but isotonic crystalloids can still be given to maintain intravascular volume, particularly in SAH patients who require volume expansion.

In most cases of SIADH, the usual treatment of oral free water restriction is slow; this treatment prevents more free water from being retained but does not eliminate the free water excess that currently exists. Addition of sodium tablets also does little to correct the problem because 2 g of sodium chloride is the equivalent of only 34 mEq of sodium chloride, an amount not nearly sufficient to correct the problem.

TABLE 125.2 Interpretation of Fractional Excretion of Sodium and Urinary Sodium Concentration

	Prerenal	Intrinsic Renal Disease	Postrenal Obstruction
FENa[a]	<1%	>1%	>4%
U_{Na} (mmol/L)	<20	>40	>40
Examples	Hypovolemia	Acute tubular necrosis	Bladder obstruction
	Heart failure	Glomerulonephritis	Ureteral obstruction
	Renal artery stenosis	Acute nephritis	

Abbreviations: FENa, fractional excretion of sodium; U_{Na}, urine sodium.
[a]FENa is calculated as $[(P_{Cr} \times U_{Na}) / (P_{Na} \times U_{Cr})] \times 100$.

Recently, a novel therapy of vasopressin receptor blockade has been introduced, which targets the V2 receptor in the distal collecting tubule. By causing a conformational change, aquaporin 2 allows more free water to exit ("aquaresis") leading to a significant free water clearance. *Tolvaptan* 15 mg orally daily leads to an average increase in serum sodium of 3 mEq/L over 24 hours, whereas *conivaptan* 20 mg intravenous over 1 hour, followed by a 20-mg infusion over 24 hours, results in a mean increase in sodium 6 mEq/L over 24 hours. By blocking the ADH receptor, so-called vaptan therapy targets the underlying pathophysiologic abnormality that underlies SIADH. Both agents have a U.S. Food and Drug Administration indication for patients with euvolemic or hypervolemic hyponatremia due to SIADH.

OSMOTIC DEMYELINATION SYNDROME

In 1959, Adams, Victor, and Mancall described a distinctive condition characterized by the symmetric destruction of myelin sheaths in the basis pontis in the setting of overly rapid correction of serum sodium. They coined the term *central pontine myelinolysis*.

Later recognition that the demyelination can affect white matter pathways outside of the pons let to the term *extrapontine myelinolysis (EPM)*. The term *osmotic demyelination syndrome* (ODS) is now used as a general descriptive term for the syndrome, with CPM and EPM being the two main anatomic variants.

ODS typically develops after overly rapid correction of chronic hyponatremia to normal or supranormal levels. Chronic alcoholism and undernutrition are frequently associated with this condition, but the underlying case of the hyponatremia can result from any cause, including SIADH; dehydration resulting from vomiting, diarrhea, or diuretic therapy; postoperative overhydration (seen most often due to bladder irrigation with urologic surgery); liver transplantation; or psychogenic water intoxication. Similarly, rapid correction of hyponatremia can lead to myelinolysis in uremics patient on hemodialysis. In addition to the underlying hyponatremia, profound hypophosphatemia, hypokalemia, and other electrolyte disorders may be present, and these abnormalities may play a role in producing the syndrome. Rarely, rapid increases in serum sodium level from a normal baseline can cause ODS in neurocritical care patients treated aggressively with bolus osmotherapy.

In most cases, the main causative factor in ODS appears to be rapid correction of serum sodium, but some instances occur in individuals with severe electrolyte abnormalities in the absence of overly rapid sodium correction. Similarly, correction of hyponatremia far exceeding the accepted safe rate of 0.5 mEq/L/hr can occur with no neurological consequences. Many variables other than the rate of correction of hyponatremia, such as coexisiting electrolyte and micronutrient deficiencies, seem to play a role in the pathogenesis of ODS.

Epidemiology

ODS is rare. In a 2011 study from Sweden that identified 83 affected patients, the overall incidence was 0.6 per million person-years. Most cases (87%) were hyponatremic at baseline, with a median sodium level of 104 mEq/L, and in all cases, the hyponatremia was chronic. The cause of hyponatremia was multifactorial, including drugs (57%), vomiting or diarrhea (42%), and polydipsia (32%), and the majority of patients (70%) were alcoholics. In another recent series from Massachusetts General Hospital, of 45 cases identified over 10 years, the most common comorbidities were alcoholism (43%), liver disease (26%), and kidney failure (20%).

Pathobiology

The principal pathologic change is demyelination. Within affected areas, there is degeneration with loss of oligodendrocytes but nerve cells and axon sheaths are spared, blood vessels are unaffected, and there is no inflammation. The pathophysiology seems caused by physiologic imbalance of osmoles in the brain. Apoptosis may deplete supply of energy to glial cells and Na^+/K^+ adenosine triphosphatase (ATPase) pumps, thus impairing cellular adaptation to osmotic stress. In animal studies, the initial event after administration of hypertonic saline in hypotonic rats seems to be opening of the blood-brain barrier, followed sequentially by swelling of the inner loop of the myelin sheath, oligodendrocyte degeneration, and release of macrophage-derived factors leading to the eventual breakdown of myelin. Histologically, the lesion begins in the median raphe and may involve all or part of the base of the pons (Fig. 125.2). The lesion may spread into

FIGURE 125.2 Central pontine myelinolysis. Histologic section through rostral pons showing characteristic lesion. (Courtesy of Dr J. Kepes.)

the pontine tegmentum or superiorly into the mesencephalon or involve bilateral extrapontine areas with or without concurrent basis pontis lesions. Microscopically, lesions resemble those of Marchiafava-Bignami disease (demyelination of corpus callosum and other commissural fibers, commonly seen in the context of chronic alcoholism and malnutrition).

The exact cause of myelinolysis is uncertain. In those with hyponatremia that has been rapidly corrected to normal or supranormal levels, it is not clear whether the low sodium, the rate of correction, or absolute change in serum sodium content is a causative factor. However, symptoms are more likely to develop with rapid correction of chronic rather than acute hyponatremia. In experimental animals, pontine myelinolysis can be produced in hyponatremic rats, rabbits, or dogs treated rapidly with hypernatremic saline. Animals left with untreated hyponatremia did not develop neuropathologic changes. Therefore, attention has focused on rate of correction of the hyponatremia as the primary inciting mechanism of myelinolysis. A recent study has suggested loss of activity of brain aquaporins (specifically aquaporins 1 and 4) affecting redistribution of water and osmolytes across various brain compartments may be seen in pontine myelinolysis.

Clinical Manifestations

Patients with ODS often have a biphasic course, the first phase reflecting the underlying predisposing illness and the second phase reflecting ODS itself. Classically, neurologic signs and symptoms of myelinolysis appear within 2 to 3 days after rapid correction of sodium levels. In CPM initial symptoms of dysarthria and dysphagia progress to flaccid and then later spastic quadriplegia. Other findings may include mutism, behavioral abnormalities, frank psychosis, ophthalmoparesis, bulbar and pseudobulbar palsy, hyperreflexia, and rarely seizures or coma. In the most severe cases of CPM, the patients may be "locked in," and communication by eye blinking can sometimes be established. EPM can lead to ataxia, irregular behavior, visual field deficits, parkinsonism, choreoathetosis, dystonia, or paroxysmal kinesigenic dyskinesias. The movement disorders can appear with or without radiographic evidence of EPM. Movement disorders as result of EPM may be treatable, with some improvement noted after dopaminergic therapy.

Diagnosis

Although historically most cases were diagnosed at autopsy, the syndrome can now easily be diagnosed in life with MRI. Computed tomography scans may be normal, especially early in the course, but may reveal symmetric areas of hypodensity in the basis pontis or extrapontine regions without associated mass effect. MRI is much more sensitive and typically shows symmetric increased signal intensity in the central pons (often described as *trident-shaped*) on T2-weighted and fluid-attenuated inversion recovery images (Fig. 125.3). The lesions appear hypointense on T1-weighted images and typically do not enhance. MRI diffusion-weighted imaging may be even more sensitive because it demonstrates increased signal of restricted diffusion of water in the central pons within 24 hours of the onset of symptoms from myelinolysis. Lesions seen within the basis pontis typically spare the tegmentum and may extend to the ventral midbrain but rarely involve the medulla. In EPM, bilateral symmetric involvement may affect white matter pathways in the basal ganglia, cerebellum, thalamus, midbrain, corpus callosum, subcortical white matter, claustrum, or medial lemnisci.

Because imaging findings may lag behind clinical manifestations for up to 2 weeks, in clinically suspicious cases with initial negative neuroimaging, repeat MRI is recommended.

Other studies that can assist in diagnosing ODS include magnetic resonance spectroscopy, which can demonstrate decreased *N*-acetylaspartate/creatine ratios and increased choline/creatine ratios, and brainstem auditory–evoked responses, which may demonstrate prolonged III to V and I to V latencies. An electroencephalogram may show slowing and low voltage. CSF levels of protein and myelin basic protein may be elevated.

Prevention and Treatment

Prevention of myelinolysis includes judicious correction of hyponatremia with normal saline and free-water restriction, discontinuation of diuretic therapy, and correction of associated metabolic abnormalities and medical complications. At present, there are no clinical trials providing Level 1 evidence for the appropriate treatment of CPM. *Based on clinical guidelines, there is a very low frequency of myelinolysis if the rate of serum sodium correction is targeted at 8, and does not exceed 12, mmol/L over 24 hours.* If the serum sodium is increased faster than this rate, it by no means ensures that ODS will occur. Rather, ODS is rarely seen if the rate of correction is within these limits. Normal (0.9%) saline (154 mEq/L sodium concentration) should generally be used as the initial resuscitation fluid, although lactated Ringer solution (130 mEq/L sodium concentration) can be used as an alternative if even slower correction is desired. A variety of online calculators (https://reference.medscape.com/calculator/643/sodium-correction-rate-for-hyponatremia) exist to provide the proper fluid infusion rate to attain a 0.33 mmol/L/h correction rate (which will produce an 8 mEq increase over 24 h).

Correction of Hyponatremia Case Example

A 54-year-old 70-kg man presents to the emergency department after a witnessed seizure. He has no history of prior epilepsy, but he admits to being a long-time alcohol user who consumes approximately one pint of vodka daily. He is afebrile, vital signs are stable, and on exam, he appears dehydrated with dry mucous membranes. On neurologic testing, he is oriented to place and year but not date and appears lethargic. Laboratory testing reveals a blood alcohol content of 45 mg/dL, a serum sodium level of 119 mEq/L, and prerenal azotemia. The diagnosis is new-onset seizures provoked by alcohol use and hyponatremia. You recommend to correct his serum sodium level by 8 mEq per 24 hours, over 2 consecutive days (0.33 mEq/h). An online calculator reveals that normal saline at a rate of 405 mL/h will be sufficient to increase his sodium level from 119 to 127 mEq/L on day 1 and from 127 to 135 mEq/L on day 2.

Hyponatremic patients who are asymptomatic from brain edema or seizures may need more rapid correction, especially if the hyponatremia is more acute. The typical approach is to give 3% hypertonic saline either as 50- to 150-mL intravenous boluses, or as a continuous infusion at 0.5 to 1.0 mL/kg/h. Caution should be used in giving hypertonic saline to patients with acute symptomatic hyponatremia; frequent laboratory evaluations of serum sodium should be used as a guide to avoid overly rapid correction of low sodium levels.

Outcome

CPM was classically reported to have an extremely high mortality, ranging from 35% to 50%, and an associated high rate of permanent neurologic disability. More recently, the outcome has been found to be remarkably more upbeat. In the aforementioned Swedish national study, after 6 months of follow-up, only 7% of ODS patients had died and 60% were functionally independent. Near-complete recovery from comatose or locked-in states has been reported. Persistent disability may manifest as the late appearance of dysarthria, ataxia, tremor, dystonia, or cognitive and behavioral changes. Prognostics factors that are favorable for recovery include younger age, less severe hyponatremia, and a less severe clinical syndrome on admission and discharge.

126 Gastric and Genitourinary Function and the Brain

Alden Doerner Rinaldi and Charles C. Esenwa

KEY POINTS

1. Gastric and genitourinary function is largely driven by autonomic outflow from the sympathetic and parasympathetic nervous systems. Their reciprocal action regulates sexual function, urinary storage, and voiding and tunes the enteric nervous system to control gut motility, secretomotor function, perfusion, fluid and nutrient absorption, and enteric immune function.
2. Injury to the nervous system at any level and by diverse mechanisms can result in myriad gastrointestinal and/or genitourinary manifestations. Identification and proper interpretation of these signs and symptoms can be helpful in both localization and diagnosis.
3. Inversely, numerous primary gastrointestinal disorders may have deleterious effects on neurologic function or lead to neurologic disease.
4. Emerging evidence links the microbiome-gut-brain axis to both neurologic health and disease, such as multiple sclerosis and stroke.

INTRODUCTION

The brain shares intricate connections with the gastrointestinal (GI) and genitourinary (GU) organ systems. Injury to the nervous system at any anatomic level and by any number of mechanisms—ischemia, trauma, inflammation, infection, toxic-metabolic insult, developmental anomaly, or degeneration—can provoke GI or GU symptoms. Inversely, primary GI disorders may have deleterious effects on neurologic function. In both cases, the human consequences in terms of quality of life, morbidity, and mortality can be enormous. Here we describe (1) the general neurologic mechanisms that lead to disruption of the healthy physiologic function of the GI and GU systems, (2) specific neurologic disorders with significant GI or GU manifestations, and (3) GI disorders frequently associated with neurologic complications.

NEUROANATOMY

The autonomic nervous system is central in the regulation of the GI and GU systems. Autonomic impulses are mediated by the cortex and hypothalamus and affect nuclei in the brainstem, thoracolumbar, and sacral spinal cord. Parasympathetic cholinergic outflow from the dorsal nucleus of the vagus nerve in the medulla promotes the vegetative functions of secretion, digestion, absorption, and gut motility, whereas sacral parasympathetics stimulate voiding, defecation, and tumescence.

Sympathetic adrenergic outflow from the thoracolumbar cord directly opposes parasympathetic function by decreasing secretions, gut motility, and splanchnic blood flow while also increasing sphincter tone to promote urinary and fecal continence. Somatic motor neurons arising from Onuf nucleus at the S2-4 segments of the sacral cord pass via the pudendal nerve to innervate muscles of the pelvic floor and sphincters at the anus and urethra maintaining volitional control over continence (Fig. 126.1).

The enteric nervous system is a quasi-independent branch of the autonomic nervous system with an estimated 400,000 to 600,000 neurons, nearly equal to that of the entire spinal cord. Its function is to (1) orchestrate gut motility, (2) control secretomotor function, (3) regulate local blood flow, (4) control fluid and nutrient absorption, and finally, (5) interact with and modulate the enteric immune system. It has two anatomically distinct subdivisions. The submucosal plexus, which includes Meissner plexus, is located in the gut wall and monitors the local epithelial environment exerting secretomotor control in response to parasympathetic stimuli, whereas the myenteric, or Auerbach, plexus located superficially in the muscular layer of the gut mediates motility through both sympathetic and parasympathetic inputs. The most proximal and distal parts of the GI tract are somatically innervated, making these areas particularly susceptible to neurologic injury.

GASTROINTESTINAL MANIFESTATIONS OF NEUROLOGIC DISEASE

Dysphagia

The process of deglutition is initiated in the cerebral cortex and overseen by the nucleus ambiguus in the medulla. Chewing, bolusing, and initiation of the swallow reflex occur in the oropharynx through a coordinated effort involving multiple cranial nerves. The swallow reflex and esophageal peristalsis are the involuntary phases and are overseen by glossopharyngeal and vagal inputs. Difficulty with swallowing, or dysphagia, can manifest as drooling, inability to effectively maneuver the food bolus, a sensation of esophageal fullness, and choking or coughing when attempting to ingest food.

A disease process affecting the primary motor cortex or supplementary motor areas, such as stroke or neurodegenerative dementia, can disrupt the preparatory and oral phases of swallowing. Direct injury to the brainstem or corticobulbar tracts by ischemia, the Parkinson-plus syndromes, or multiple sclerosis (MS) can disrupt inputs to the nucleus ambiguus, affecting the involuntary phase of swallowing. Motor neuron disorders such as amyotrophic lateral sclerosis (ALS) (Lou Gehrig disease) or spinal and bulbar muscular atrophy (Kennedy disease)

FIGURE 126.1 Peripheral neuroanatomy of the gastrointestinal (GI) and genitourinary systems. Somatic innervation predominantly by cranial nerves (CN) V, VII, IX, and XI as well as the pudendal nerves appear in yellow. Parasympathetic innervation, depicted in red, is carried rostrally from the brainstem to the oropharynx and proximal enteric nervous system by the vagus nerve (CN X). Caudal parasympathetic innervation arising from the sacral cord, instead, travels by way of the pelvic nerves. Sympathetic output, in blue, on the other hand, reaches the enteric nervous system by way of three principle ganglia—the celiac, superior, and inferior mesenteric. The pelvic organs receive their sympathetic innervation via the hypogastric nerve, which complexes with sacral parasympathetic outputs at the pelvic to richly innervate the distal colon, rectum, and genitourinary organs. Abbreviations: C, cervical; ENS, enteric nervous system; L, lumbar; S, sacral; T, thoracic.

cause prominent dysphagia by affecting the motor neurons that supply the muscles of mastication, the oropharynx, and upper esophagus. Peripherally, disorders of the neuromuscular junction, such as myasthenia gravis and botulism, and disorders of muscle, including the muscular dystrophies and inflammatory myopathies, can also have significant effects on all phases of deglutition.

Current guidelines in stroke call for dysphagia screening to be done in all patients hospitalized for acute stroke. Screening protocols vary and include cough reflex testing, bedside swallowing tests, or comprehensive assessment by a speech language pathologist LEVEL 1.[1]

Videofluoroscopy has been the gold standard in the evaluation of dysphagia, and direct visualization using videoendoscopy is now being used more commonly to objectively evaluate swallowing function in patients who have failed dysphagia screening. Although texture-modified foods and thickened liquids are often used to decrease aspiration risk, patients with severe dysphagia or those who are deemed unable to meet their free-water or nutritional requirement for more than 7 days should be considered for percutaneous endoscopic gastrostomy (PEG) placement. In stroke where deglutition is expected to recover, PEG is often temporary and primarily used as a bridge to independent swallowing LEVEL 1.[2]

Oropharyngeal dysphagia due to a degenerative disorder, although mitigated by swallow therapy, will naturally progress to malnutrition, dehydration, and ultimately carries a high risk of aspiration pneumonia. It is therefore recommended that patients with ALS or Parkinson disease (PD) participate in routine screening questionnaires to assess for dysphagia and malnutrition. Similar to stroke, dysphagia screening methods videofluoroscopy and videoendoscopy should be used to objectively evaluate swallow function. A PEG placement in patients with ALS confers a significant survival benefit of 20 months, and trade-offs should be discussed early in the disease course LEVEL 1.[3] In contrast, PEG placement in patients with dementia leads has worse outcomes when compared to both nondementia patients receiving PEG placement and dementia patients not receiving PEG placement. Factors contributing to poor outcomes include overall poor prognosis in advanced dementia, increased risk of aspiration pneumonia, increased urinary and fecal incontinence contributing to decubitus ulcers and infections, and increased use of restraints. As such, multiple guidelines recommend against PEG insertion for patients with advanced dementia LEVEL 1.[4]

Esophageal Dysmotility

The lower esophageal sphincter is controlled by the dorsal motor nucleus of the vagus nerve and is meant to serve as a one-way valve for food contents passing from the esophagus to the stomach. Achalasia is characterized by loss of esophageal peristalsis with sustained contraction of lower esophageal sphincter leading to megaesophagus and a classic "bird's beak" appearance on videofluoroscopy. Although typically a primary idiopathic disorder, there is evidence implicating an underlying inflammatory or autoimmune process affecting the ganglion cells of the myenteric plexus. Similarly, in the chronic stages of Chagas disease, achalasia can occur by infectious destruction of the myenteric plexus by the protozoa *Trypanosoma cruzi*.

Gastroparesis

Peristalsis in the stomach is controlled by independent rhythmic contractile waves paced by the interstitial cells of Cajal and overseen by vagal inputs. Gastroparesis, or delayed gastric emptying from impaired antral motility, usually presents as postprandial bloating, pain, nausea, and vomiting. Diabetic vagal neuropathy and diabetic autonomic neuropathy are common causes that can similarly affect bowel motility, causing alternating diarrhea and constipation. Prokinetic agents such as metoclopramide, cisapride, and erythromycin are used to treat acute exacerbations, whereas severe cases may require venting gastrostomy with feeding enterostomy.

Stress Gastric Ulcer

Neurologic dysfunction from traumatic brain injury, spinal cord injury, or neurologic surgery predisposes to stress-related mucosal injury and hemorrhage. Stress ulcers are particularly exacerbated by injury involving brainstem and diencephalon. Dysregulation of hypothalamic function with simultaneous overactivation of parasympathetic and sympathetic efferents both increase gastric acid production and compromise mucosal protection. Stress ulcer prophylaxis is recommended in patients with coagulopathy or those requiring mechanical ventilation but should also be considered in patients with traumatic brain or spinal cord injury. Proton pump inhibitors serve as first-line therapy.

Bowel Dysmotility

Motility of the small and large intestines is coordinated exclusively by reflex loops made up of motor neurons, interneurons, and intrinsic sensory neurons. Primary Hirschsprung disease is a condition in which this neuronal network fails to form. Failure of neural crest cells to migrate during development leaves a section of colon or rectum without functional enteric plexus. Newborns can have delay in passage of meconium and in severe instances will have massive secondary dilation of the bowel termed *megacolon*. In less severe cases, diagnosis can be delayed to late childhood and even adulthood. Patients in this subgroup come to medical attention because of chronic symptoms of constipation. Diagnosis is suggested by videofluoroscopy and is made by rectal biopsy. Surgical resection of the affected bowel is the mainstay in treatment. Destruction of the enteric plexus by *T cruzi* infection in Chagas disease is a secondary form of megacolon that has a similar diagnostic and therapeutic approach.

Incontinence

Much like the esophagus, autonomic and somatic nerves innervate the anorectum. Reflex muscle contractions and paired inhibitions drive fecal movements through the rectum and into the anal vault. Motor neurons arising from Onuf nucleus at the sacral level traverse the lower sacral plexus and pudendal nerves, ultimately exerting their effect on the external anal sphincter and muscles of the pelvic floor. Lower motor neuron injuries at this level cause sphincter dysfunction with loss of formed stool and fecal incontinence. Anorectal manometry and anal sphincter electromyography have diagnostic value in such cases.

URINARY MANIFESTATIONS OF NEUROLOGIC DISEASE

The lower urinary tract serves as both reservoir and outlet by the reciprocal action of detrusor and urethral sphincter muscles. Anatomically, the periaqueductal gray, located in the pons, integrates rostral input from the midbrain, limbic system, and cortex to promote bladder compliance and storage through a direct tonic inhibition of the pontine micturition center (PMC). This inhibition results in a *storage reflex* by which suppression of parasympathetic and activation of sympathetic pathways causes synergistic detrusor relaxation and urethral smooth muscle contraction to close the urethral outlet. A *voiding reflex* is similarly directed by the periaqueductal gray, whereby release of the PMC activates parasympathetically driven circuits throughout the thoracosacral spinal cord. Cholinergic stimulation contracts the bladder, whereas nitric oxide released from nonadrenergic noncholinergic parasympathetic fibers relaxes the internal urethral sphincter. This action is facilitated by volitional control of somatically innervated striated muscle of the external urethral sphincter to open the urethral outlet and permit micturition. These distinct reflexes may be disrupted by neurologic injury leading to symptoms that are broadly classifiable as (1) *voiding dysfunction* with hesitancy, intermittency, slow stream, straining, terminal dribble, and retention or (2) *storage dysfunction* with urgency, frequency, nocturia, incontinence, and altered bladder sensation (Fig. 126.2).

Voiding Dysfunction

Lower motor neuron lesions of the sacral roots, plexus, or peripheral nerves cause parasympathetic denervation of the detrusor muscle resulting in a large, areflexic, and underactive bladder. When occurring alone, functional voiding symptoms may be difficult to differentiate from urinary outlet obstruction, but decreased rectal tone and impaired defecation often accompany. In the extreme form, the patient will have acute urinary retention, which is a urologic emergency. Causes include spinal cord shock from traumatic injury, Guillain-Barré syndrome, conus medullaris syndrome, and cauda equina syndrome; however, additional neurologic symptoms such as sensory loss, weakness, and areflexia will typically predominate in all of these. Less commonly, acute infection of the sacral roots by varicella or herpesviruses can also cause urinary retention accompanied by unilateral sacral pain, sensory loss, and classic zoster or herpetic rash. Opiates, anticholinergic medications, α-adrenoreceptor agonists, benzodiazepines, nonsteroidal anti-inflammatory agents, and calcium channel blockers can all cause reversible voiding dysfunction.

Upper motor neuron lesions of the spinal cord can functionally uncouple the reciprocal action of the pathways responsible for bladder control. Although typically associated with storage dysfunction, it can cause detrusor sphincter dyssynergia with intermittent and simultaneous contraction of the detrusor and urethral sphincter muscles and resultant urinary retention accompanied by hesitancy and interrupted stream.

Bladder scan, postvoid residuals, urinalysis, and voiding diary will help assess degree of dysfunction, whereas spinal magnetic resonance imaging, clinical neurophysiology, and lumbar puncture can help to determine the underlying etiology. Patients with either acute or chronic voiding dysfunction are at high risk

FIGURE 126.2 Symptoms of neurogenic bladder dysfunction. Particular bladder symptoms may be classified as relating to voiding dysfunction, storage dysfunction, or a mixed picture in which both occur simultaneously. Pure voiding (purple area) and storage (coral area) dysfunction are synonymous with detrusor areflexia and detrusor overactivity, respectively, whereas a combination of voiding and storage dysfunction (area of overlap) will lead to detrusor sphincter dyssynergia. Each condition leads to its own unique pattern of symptomology as listed. Abbreviation: OAB, overactive bladder.

of developing urinary tract infections and bladder stones and may require intermittent urethral catheterization or a continuous suprapubic catheter. Less definitive symptomatic management may include reflex voiding by suprapubic pressure (Credé maneuver), vibratory stimulation, or cold water applied to the genitals. Detrusor areflexia has a variable response to muscarinic receptor agonists or a parasympathomimetic agent such as bethanechol. Relaxation of the urethral sphincter by baclofen, α-adrenergic blockade, or intrasphincteric botulinum toxin injection can provide additional benefit.

Storage Dysfunction

Upper motor neuron injury, either above or below the level of the pons, can result in detrusor overactivity. Typically, the bladder is small and hyperreflexic. The patient will suffer from increased urinary frequency, urgency, and incontinence, a symptomatic triad commonly referred to as *overactive bladder (OAB) syndrome*. A chronic elevation of intravesicular pressures results and over time can lead to detrusor hypertrophy, vesicoureteric reflux, hydronephrosis, renal impairment, and even end-stage renal disease. Here too, urodynamic testing should be pursued to better assess the pathology and help plan more invasive management of refractory symptoms.

Therapeutic approaches to storage dysfunction address OAB symptoms while mitigating the long-term consequences of persistently elevated bladder pressure. Nonpharmacologic interventions such as avoiding caffeine, pelvic floor exercises, and bladder training may be efficacious for mild symptoms. Antimuscarinic agents improve bladder compliance and are considered the mainstay of pharmacotherapy. Their use is sometimes limited by adverse central nervous system (CNS) effects, constipation, and urinary retention, in which case muscarinic acetylcholine receptor M_3 specific or blood-brain barrier impermeable agents, such as darifenacin and trospium, can be employed. Desmopressin can also reduce symptoms of urinary frequency but does so by decreasing urine production. When OAB symptoms persist despite optimal pharmacotherapy, intradetrusor botulinum toxin injection may be an effective and minimally invasive treatment to reduce urinary incontinence and improve quality of life. Treatment efficacy lasts, on average, 9 to 10 months with persistent benefit using repeated treatment. Additional second-line treatment options include sacral neuromodulation and posterior tibial nerve stimulation. As an option of last resort, surgical augmentation by cystoplasty, urinary diversion, or sphincterotomy can be done to definitively reduce bladder pressures.

SEXUAL MANIFESTATIONS OF NEUROLOGIC DISEASE

The medial preoptic area of the hypothalamus mediates sexual stimuli and initiates the sexual response. Caudal projections to midbrain and brainstem nuclei—including the paraventricular nucleus of the hypothalamus, the ventral tegmental area, the raphe, and gigantocellular nuclei—drive spinal reflexes that initiate tumescence, emission, and ejaculation. Tumescence may occur by both psychogenic and reflexogenic mechanisms driven by cerebrum and spinal cord, respectively. A preponderance of parasympathetic tone transmitted via the pelvic plexus and cavernous nerves to the genital soft tissue relaxes the smooth muscle of the corpora cavernosa and helicine penile arteries. Nitric oxide released from nonadrenergic noncholinergic parasympathetic fibers further increases blood flow and intracavernosal pressure. Subsequent venous compression against the tunic albuginea restricts the outflow of blood to enhance and maintain erection. In women, tumescence occurs with increased vaginal blood flow and lubrication. Afferent signals carried by the pudendal and

hypogastric nerves are distributed rostrally throughout the CNS. As sexual stimulation increases, sympathetic tone builds with glandular emission of the various components of sperm and the formation of semen. At sexual climax, sympathetic surge through the hypogastric nerves results in a coordinated autonomic and somatic reflex. In the male, this results is simultaneous closure of the bladder neck and expulsion of semen by rhythmic contractions of striated muscle.

Female Sexual Dysfunction

Female sexual dysfunction (FSD) is a frequent, although poorly explored, comorbidity of neurologic disease, which may be categorized as disorder of sexual desire, arousal, orgasm, or sexual pain. The FSD negatively impacts quality of life, both directly and by compromising sexual relationships and, thereby, psychosocial health. The prevalence of FSD in MS is double that of the general population with more than 80% of female MS patients reporting symptoms of low desire, decreased arousal, and difficulty achieving orgasm. In MS, these symptoms of sexual dysfunction typically correlate with impaired cognitive function, depressive symptoms, bladder and bowel incontinence, Expanded Disability Status Scale scores, and MS subtype but not time since diagnosis. Similarly, FSD is overrepresented among women with epilepsy, most commonly as a lack of sexual desire and orgasmic dysfunction. Both dysregulated hypothalamic function due to ictal and interictal discharges and effects of enzyme-inducing drugs on circulating testosterone levels may contribute. Given the clear importance of sexual health on overall quality of life, a detailed sexual history should be included in any comprehensive neurologic assessment exploring any impediment to healthy sexual function, satisfaction, and relationship.

Male Sexual Dysfunction

Injury rostral to the thoracolumbar cord preserves reflexogenic erection and ejaculation but blocks the psychogenic facilitation of the human sexual response resulting in difficulty maintaining erection. Disconnecting sympathetic pathways by injury to either the thoracolumbar cord or hypogastric nerves, often by lymph node dissection or sigmoidectomy, similarly spares reflexogenic erection but frequently inhibits ejaculation. Sacral spinal cord and root injury, on the other hand, interrupts parasympathetic outflow and reflexogenic sexual response. Plasticity of thoracolumbar outputs to the pelvic plexus provides an alternative pathway by which psychogenic erection and ejaculation may reemerge.

Phosphodiesterase-5 inhibitors improve erectile function, but their use must be weighed against the cardiovascular side effects, to which neurologic patients with autonomic dysfunction are particularly prone. Apomorphine, a dopamine agonist, acts centrally to initiate erection but requires intact efferent spinal pathways to be of benefit. Intracavernous injections of prostaglandin E1, papaverine, and phentolamine as well as intraurethral alprostadil are effective second-line therapies. Ejaculatory dysfunction and sexual function in general may be treated with yohimbine, a mild monoamine oxidase inhibitor, whereas midodrine, an α_1 agonist, has been shown effective in facilitating ejaculation in men with spinal cord injury. In addition, an array of mechanical and electrostimulatory techniques for men may enable sexual function, reproduction, and improve quality of life.

NEUROLOGIC DISORDERS AND THE GASTROINTESTINAL AND GENITOURINARY SYSTEMS

Peripheral Neuropathy

Peripheral autonomic fibers are particularly susceptible to neuropathy with resultant and often concurrent cardiovascular, GI, and GU dysfunction. Acute cholinergic neuropathies are the exception, causing isolated GI and GU manifestations. The GI symptomology includes postprandial fullness, nausea, paralytic ileus, constipation, intermittent diarrhea, and bowel incontinence. The GU symptoms are also varied, but urinary retention and erectile dysfunction, a sensitive indicator of early autonomic dysfunction, predominate. Diabetes mellitus is the most common cause of autonomic neuropathy. The lower urinary tract symptoms, gastroparesis, and constipation are present in over half of diabetic patients. Pudendal compressive injury, known as *Alcock syndrome*, is classically associated with bicycle riding or labor and results in genital sensory loss, erectile dysfunction, and fecal and urinary incontinence.

Spinal Cord Injury

Spina bifida is one of the most common birth defects worldwide with an incidence of 1 or 2 per 1,000 births. In addition to lower extremity weakness and orthopedic problems, decreased bladder sensation and storage dysfunction commonly occur. This developmental anomaly or its surgical correction is also associated with tethered cord syndrome with traction of the filum terminale and displacement of the conus medullaris below the L1-2 disk space. As a consequence, flexion or extension of the spine may provoke pain, sphincter dysfunction, and incontinence.

In the acute phase of traumatic spinal cord injury, autonomic and reflex activities may be lost below the level of injury with paralytic ileus and voiding dysfunction. In the chronic phase, these disabled reflexes reemerge with exaggerated function. Hyperreflexia and loss of voluntary control increases bladder and colon wall tone and tightens the external anal sphincter leading to OAB with simultaneous constipation and mild incontinence. Chronic constipation requires attentive bowel care to help prevent stercoral rectal ulcers. With spinal cord transection at or above the level of T6, potentially fatal autonomic dysreflexia can occur after an uninhibited sympathetic surge is triggered by a noxious stimulus, such as bladder or bowel distention.

Multiple Sclerosis

Bladder dysfunction is common in MS, affecting 80% to 100% of patients over the course of their disease. Given that there are often incomplete and multilevel spinal cord lesions, patients usually give a mixed picture of urinary tract dysfunction, although storage dysfunction with OAB is most frequently encountered. In addition to conventional approaches outlined earlier, cannabis and the cannabinoid-derived nabiximol have shown modest results in increasing bladder control and improving quality of life. Sexual dysfunction affects more than half of men and women with MS. Decreased libido and arousal; dyspareunia; and inability to achieve erection, orgasm, and ejaculation may be further compounded by associated fatigue, immobility, and allodynia.

Parkinsonism

Patients with PD have been shown to develop Lewy body pathology in the enteric nervous system early in the course of the disease. Moreover, involvement of the dorsal motor nucleus of the vagus nerve causes parasympathetic dysfunction and prominent gastric symptoms. Dysphagia with pooling of saliva and drooling, postprandial fullness from delayed gastric emptying, bowel dysmotility, and constipation frequently occur. Loss of libido and erectile and ejaculatory dysfunction are also common. Pathologic hypersexuality, however, may be seen in the setting of dopamine dysregulation syndrome. Late in the disease course, there can be loss in dopamine-mediated inhibition of the PMC leading to urinary storage dysfunction and OAB.

Multiple system atrophy (MSA) is characterized by ubiquitin and α-synuclein inclusion bodies and cell loss in the brainstem, basal ganglia, cerebellum, motor cortex, and central autonomic system with subsequent autonomic failure, parkinsonism, cerebellar ataxia, and pyramidal signs. Compared to PD, urogenital dysfunction is a relatively early feature. Erectile dysfunction is the initial symptom in an estimated 41% of male patients and eventually affects almost all men with MSA. Symptoms of voiding dysfunction and urinary retention develop early in the course of the disease. As a consequence, more than half of patients with MSA suffer from recurrent urinary tract infections.

Cortical and Subcortical Disease

Urodynamic testing in patients with cortical neurodegenerative disorders such as Lewy body dementia and Alzheimer disease frequently demonstrates subclinical storage dysfunction. In normal pressure hydrocephalus, incontinence is usually the presenting symptom in the triad of gait disturbance and cognitive impairment. Detrusor overactivity is the most common form of incontinence after stroke and has a significant impact on post-stroke quality of life. Even subclinical leukoaraiosis is thought to contribute to storage dysfunction. The shared mechanism across these disparate conditions is thought to be disruption of frontal white matter tracts.

NEUROLOGIC CONSEQUENCES OF PRIMARY GASTROINTESTINAL DISEASE

Irritable bowel syndrome is a common GI syndrome that affects up to 20% of adults. It is defined by cramping abdominal pain, altered bowel habits, and changes in stool form and frequency. The underlying cause, although largely unknown, has been related to abnormally low threshold for neurogenic gut simulation by inflammatory mediators such as serotonin, histamine, and corticotropin-releasing factor resulting in dysregulated postprandial gut motility and visceral hyperalgesia.

Gluten sensitivity and celiac disease cause small bowel inflammation with dietary exposure to gluten. Diverse neurologic manifestations can occur, often before the GI symptoms are apparent. Gluten ataxia typically presents insidiously in the fifth decade of life as pure cerebellar ataxia. It can be accompanied by myoclonus, opsoclonus, palatal tremor, or chorea. A majority will have cerebellar atrophy on imaging. Nearly a quarter of patients with established celiac disease on a gluten-free diet will have electrophysiologic evidence of peripheral nerve damage. Although most commonly a sensorimotor axonal neuropathy, sensory ganglionopathy, small-fiber neuropathy, and pure motor neuropathy have been reported. Rarely, encephalopathy with headaches, diffuse or focal CNS white matter abnormalities, and cognitive deficits can be seen in association. Gradually progressive white matter disease can also occur and may be difficult to distinguish from MS. Other neurologic disorders reported in association with gluten sensitivity include stiff person syndrome, myopathy, and myelopathy. The common mechanism for these varied clinical manifestations is thought to involve perivascular inflammation, breakdown of the blood-brain barrier, and loss of the CNS immunoprivilege.

Inflammatory bowel disease (IBD) is made up of two entities: ulcerative colitis and Crohn disease. Similar to gluten sensitivity, neurologic presentations of IBD occasionally precede GI symptoms and involve both the central and peripheral nervous systems. Peripheral neuropathies, including chronic-demyelinating or large- and small-fiber axonal types, are the most common neurologic complications affecting approximately one-third of patients and are typically unresponsive to the treatment of underlying IBD.

The IBD is a hypercoagulable state with increased levels of factors V and VII, fibrinogen, and von Willebrand factor; decreased levels of protein S and antithrombin; and thrombocytosis and platelet dysfunction. Cerebral venous thrombosis is a common neurologic manifestation of ulcerative colitis. An IBD-related arterial ischemic stroke can also occur and can have multiple underlying etiologies including small-vessel disease, artery-to-artery embolism, cardioembolism with or without endocarditis, paradoxical embolism, or vasculitis. Melkersson-Rosenthal syndrome has been described in patients with IBD and is characterized by a triad of recurrent orofacial swelling, relapsing facial paralysis, and fissured tongue.

THE MICROBIOME-GUT-BRAIN AXIS AND NEUROLOGIC DISEASE

The human GI system contains a complex ecosystem of bacteria, fungi, archaea, and viruses. These far outnumber the constituent cells of the human host and inhabit specific niches across the estimated 32 m^2 of surface area lining the gut lumen. This commensal metagenome, although relatively stable across small populations, is individually unique. In addition to evolving predictably over the life course, the microbiome is altered by environmental, nutritional, host immune, and other physiologic factors. Reciprocal actions of host and microbiome are critical to normal development and global regulatory function. As such, the microbiome is increasingly viewed as a vital organ in its own right—one that is integral to host health with dysbiosis or pathologic perturbation in diversity and specific composition implicated in an array of diverse pathology including, intriguingly, neurologic disease.

The human microbiome-gut-brain axis communicates bidirectionally. Vagal stimulation of the neural plexus affects expression of antibodies, antigens, and inflammatory factors which, in turn, impact the composition and activity of the gut microbiome. The afferent vagus senses local microbial metabolites as well as the gut peptides, ghrelin and leptin, at the enormous, permeable interface of the gut with modulatory effects on the hypothalamic-pituitary axis. The blood-brain barrier and brain lymphatic vasculature serve as additional gateways to the CNS

with recirculating intestinal immune cells, microbe-associated molecular patterns, and microbially produced metabolites and neurotransmitters mediating microglial maturation and activation, neurogenesis, synaptic pruning, and brain inflammatory response.

The rise of high-throughput sequencing has allowed scientists to better characterize the metagenomic makeup of the human intestinal tract in health and disease. This bidirectional microbiome-gut-brain axis has been shown to be dysregulated across numerous psychiatric, neurodevelopmental, cerebrovascular, neuro-inflammatory, and neurodegenerative disease states. For example, differences in species diversity and redundancy occur in autism spectrum disorder and depression compared to healthy controls. Similarly, the microbiome of the frail elderly is less diverse and, therefore, more vulnerable to environmental perturbation compared to young adults. Dysbiosis also results in shifts in circulating T-cell subpopulations primed in the gut with T helper and regulatory cells conferring proinflammatory and neuroprotective effects, respectively, in both MS and stroke.

Emerging association studies have shown differences in the microbiome of patients with neuroinflammatory conditions, mainly MS and neuromyelitis optica, as well as neurodegenerative diseases including Alzheimer dementia, parkinsonism, MSA, and even mild cognitive impairment when compared to controls. In cerebrovascular disease, the microbial metabolite—trimethylamine N-oxide—has atherogenic and thrombotic properties thought to confer stroke risk. Colonic biopsies and fecal samples from patients with PD show elevated inflammatory markers. Enteroendocrine cells express α-synuclein in response to inflammation, which they can transmit to enteric neurons. According to Braak's "dual-hit hypothesis," early α-synuclein deposition in the enteric nervous system and olfactory bulb ascends the vagus to aggregate in the CNS resulting in irreversible degeneration of dopaminergic neurons in the substantia nigra and elsewhere. This is supported by neuropathologic studies showing early Lewy body accumulation in the enteric nervous system and dorsal motor nucleus of the vagus with correlation to motor and GI symptom severity.

Despite the interest and numerous studies in the field, clear casual associations are lacking. Nevertheless, the microbiome shows significant promise as a clinical biomarker of neurologic disease onset, progression, and response to medical therapy.

127 Bone Diseases and the Central Nervous System

Roger N. Rosenberg and Alison M. Pack

KEY POINTS

1. Multiple disorders involving the skeletal system including Paget disease, fibrous dysplasia, and achondroplasia have neurologic manifestations.
2. Treatment of neurologic manifestations of disorders of skeleton is directed by treatment of underlying skeletal disease.
3. Neurologic diseases including epilepsy, stroke, Parkinson disease, and multiple sclerosis are associated with increased risk of osteoporosis and fracture.
4. Identifying and treating vitamin D deficiency, treating osteoporosis, and preventing falls may reduce risk of fracture in patients with chronic neurologic diseases.

PAGET DISEASE

Introduction

This chronic disease of the adult skeleton, formerly known as *osteitis deformans*, is characterized by bowing and irregular flattening of the bones. Any or all skeletal bones may be affected, but the tibia, skull, and pelvis are the most frequent sites. Usually, multiple bones are affected, but in 15%, only one is involved. The disease is symptomatic in 15% to 20% of affected individuals. Pain is the most common symptom. Except for the skeletal deformities and pain, the disease causes disability only when the skull or spine is involved.

Two types of neurologic symptoms appear: those owing to the abnormalities in bone and those owing to arteriosclerosis, a common accompaniment. The cerebral manifestations that occur with arteriosclerosis are identical to those seen in patients with arteriosclerosis in the absence of Paget disease.

Epidemiology

There is a postmortem incidence of 3% in patients older than 40 years of age. Men and women are equally affected. The most common age at onset is in the fourth to sixth decades; it is rare before age 30 years.

Pathobiology

Genetic and environmental factors such as paramyxovirus infection and dietary deficiency of calcium may influence the presentation. In affected bones, there is an imbalance between the formation and the resorption of bone. In most cases, there is a mixture of excessive bone formation and bone destruction. The areas of bone destruction are filled with hyperplastic vascular connective tissue. New bone formation may occur in the destroyed areas in an irregular disorganized manner. The metabolic disturbance is unknown.

The neurologic defects of osteitis deformans are usually related to pressure on the central nervous system or nerve roots by the overgrowth of bone. Convulsive seizures, generalized or neuralgic head pain, cranial nerve palsies, and paraplegia occur in a few cases. Deafness caused by pressure on the auditory nerves is the most common symptom; unilateral facial palsy is the next most common. Loss of vision in one eye, visual field defects, or exophthalmos may occur when the sphenoid bone is affected. Compression of the spinal cord is more common than compression of the brain, which is extremely rare except when there is sarcomatous degeneration of the lesions. Platybasia may occur in advanced cases. Paget disease has also been described in a patient with basilar impression and Arnold-Chiari type I malformation.

Diagnosis

The diagnosis of Paget disease is made from the patient's appearance and the characteristic radiographic changes. Involvement of the skull in advanced cases is manifested by a generalized enlargement of the calvarium, anteroflexion of the head, and depression of the chin on the chest. When the spine is involved, the patient's stature is shortened, the spine is flexed forward, and spinal mobility is greatly reduced.

Radiographically, the skull shows areas of increased bone density with loss of normal architecture, mingled with areas in which the density of the bone is decreased (**Fig. 127.1**). The margins of the bones are fuzzy and indistinct. The general appearance is that of an enormous skull with the bones of the vault covered with cotton wool. In advanced cases, there may be a flattening of the base of the skull on the cervical vertebrae (*platybasia*) with signs of damage to the lower cranial nerves, medulla, or cerebellum. Both computed tomography (CT) and magnetic resonance imaging (MRI) aid diagnosis.

The serum calcium content is normal, and the serum phosphorus is normal or only slightly increased. Serum alkaline phosphatase activity is increased; the level varies with the extent and activity of the process. It may be only slightly elevated when the disease is localized to one or two bones.

Diagnosis may be difficult if the clinical symptoms are mainly neurologic. In these instances, radiographs of the pelvis and legs or a general survey of the entire skeleton may establish the diagnosis. Rarely, it may be impossible to distinguish monophasic Paget disease of the skull from osteoblastic metastases. Search for a primary neoplasm, particularly in the prostate, or biopsy of one of the lesions in the skull may be necessary in those cases.

FIGURE 127.1 Osteitis deformans (Paget disease) of the skull. (Courtesy of Dr. Juan Taveras.)

Management

Bisphosphonates such as pamidronate, alendronate, risedronate, and zoledronic acid are considered the treatment of choice. These agents inhibit osteoblastic bone resorption. They have been shown to heal radiologic lesions and restore normal histology. The long-term effects of these drugs on disease progression have not been adequately studied. The most common indication is for pain. Less potent second-line choices include etidronate and tiludronate. Calcium and vitamin D repletion is necessary to avoid hypocalcemia secondary to bisphosphonates. The value of these medical therapies can be evaluated by reduction of serum levels of alkaline phosphatase measured at 4-month intervals and annual radiographs of specific lesions. Decompression of the spinal cord may be indicated for myelopathy secondary to stenosis created by the enlarged vertebrae. Similarly, platybasia may require to decompression of the posterior fossa to relieve cranial nerve dysfunction.

Calcitonin may also be given to inhibit the osteolytic process. Salmon calcitonin is given in subcutaneous injections of 50 to 100 units daily. Improvement of osteolytic lesions and reversal of neurologic manifestations have been noted with long-term therapy. About 25% of the patients develop serum antibodies to salmon calcitonin, sometimes in titers high enough to make the person resistant to the hormonal action of calcitonin; under these circumstances, human calcitonin may be effective.

Outcome

The course is variable but usually extends for decades. The neurologic lesions seldom lead to serious disability other than deafness, convulsive seizures, or compression of the spinal cord.

FIBROUS DYSPLASIA

Introduction

Fibrous dysplasia is a pathologic process characterized by small areas of bone destruction or massive sclerotic overgrowth. The skull and the bones in other parts of the body may be involved. The clinical picture of fibrous dysplasia is related to the site and extent of the bone overgrowth. Fibrous dysplasia can involve one (monostotic form) or multiple (polyostotic form) bones. Both types may be associated with hyperfunctional endocrinopathies and café au lait lesions referred to as the *McCune-Albright syndrome*.

Epidemiology

Symptoms may begin at any age, but onset usually occurs in early adult life. There is no racial or sexual predominance.

Pathobiology

Fibrous dysplasia and McCune-Albright syndrome are caused by a sporadic postzygotic missense mutation in the somatic cells of

FIGURE 127.2 Fibrous dysplasia. Computed tomography. **A:** Axial contrast-enhanced scan shows proptosis on *right* with abnormal soft-tissue enhancement within orbit and middle cranial fossa. **B:** Bone window depicts pronounced thickening of sphenoid bone. (Courtesy of Dr. T. L. Chi.)

the GNAS complex locus located on chromosome 20q13. Overall, this leads to defects in osteoblast differentiation and proliferation of osteoblast progenitors leading to abnormal bone.

Diagnosis

Diagnosis is typically made clinically after complete staging of skeletal, endocrine, soft tissue, and dermatologic features. In addition to the disfiguration of the skull in the polyostotic form, symptoms of the monostotic form of the disease include headache, convulsions, exophthalmos, optic atrophy, and deafness. Most patients are, however, asymptomatic.

Radiographic features of the skull and craniofacial bones include bone expansion showing ground-glass appearance and calvarial deformity resulting in exophthalmos. The bones of the skull most often affected are the frontal (56%) and sphenoid (48%) bones. A Danish case series of 26 subjects revealed that 80% had involvement of craniofacial bones. Diffuse involvement of the entire skull produces leontiasis ossea, with exophthalmos, optic atrophy, and cranial nerve palsies (Fig. 127.2).

Management

Treatment is limited. Surgical intervention can be used to treat fracture and bony deformities. Bisphosphonates have been used to treat bone pain. A double-blind placebo-controlled trial of alendronate, an oral bisphosphonate, found no significant effect on serum osteocalcin (a marker of bone formation), pain, or functional parameters. Intravenous bisphosphonates, pamidronate and zoledronate, may be considered, but no randomized trial has been done to support an effect. Denosumab, a RANKL inhibitor, in preliminary studies is promising for patients who are refractory to bisphosphonates.

Outcome

As treatment options are limited, children and adults with fibrous dysplasia report poor physical function and pain. A small survey study did, however, find that despite functional limitations, patients with fibrous dysplasia achieved a high level of emotional and emotional function.

ACHONDROPLASIA

Introduction

Achondroplasia (*chondrodystrophy*) is the most frequent form of skeletal dysplasia causing dwarfism and is characterized by short arms and legs, lumbar lordosis, and enlargement of the head. Symptoms of nervous system involvement sometimes develop as a result of hydrocephalus, compression of the medulla and cervical cord at the level of the foramen magnum, compression of the spinal cord by ruptured intervertebral disk, and bone compression of the lower thoracic or lumbar cord. Seizures, ataxia, and paraplegia are the most common symptoms. Mental development is usually normal. Mortality rates are significantly elevated secondary to accidental, neurologic, and heart disease–related causes. Many affected infants die in the perinatal period, although a normal life span is possible for patients with less severe involvement of the bones.

Epidemiology

The disease is rare, estimated to occur in about 1 in 15,000 to 35,000 births. Males and females are affected equally. Fathers of age 35 years and older have a relatively higher risk of having an infant with de novo achondroplasia than younger fathers.

Pathobiology

Achondroplasia is caused by mutations (G1138A and G1138C) in the fibroblast growth factor receptor 3 gene. The gene product is expressed in cartilage. The mutations result in a gain of negative function, producing an inactive fibroblast growth factor receptor and resultant dwarfism. Achondroplasia is inherited as an autosomal dominant trait, although 80% of cases are sporadic.

Diagnosis

The characteristic body configuration of short arms and legs, normal-sized trunk, enlargement of the head, and changes in the radiographs of the skeleton leads to the diagnosis. Previously, CT was used to evaluate neurologic complications of achondroplasia. Currently, MRI of the brain and spine best define the presence of hydrocephalus and degree of ventricular compensation as well as whether cord compression is present. Somatosensory evoked potential may be useful for detecting cervical myelopathy.

Management

Shunting procedures may be needed for hydrocephalus caused by involvement of the bones at the base of the skull. Laminectomy is indicated for signs of cord compression.

Outcome

As no clear treatment is available for achondroplasia, patients report long-term physical and mental impairments. Studies find that adults and children with achondroplasia have lower quality of life and lower self-esteem when compared to either healthy relatives or compared to a healthy reference population.

ANKYLOSING SPONDYLITIS

Introduction

Ankylosing spondylitis is considered the prototype of the spondyloarthropathies. Neurologic symptoms have been considered to be uncommon but have only received limited study. A study investigated this question further among 24 patients recruited from an Egyptian outpatient rheumatologic clinic compared to age- and sex-matched controls. Neurologic manifestations occurred in 25% of the patients; 8.3% had myelopathy and 16.7% had radiculopathy. Subclinical neurologic complications as evident by neurophysiologic test abnormalities were common, as over 70% had at least one abnormal finding.

Epidemiology

The condition is common, affecting an estimated 1.4% of the general population. It typically occurs in younger persons, and men are affected 2 to 3 times more commonly than women.

Pathobiology

Its etiology is likely secondary to multiple genetic and environmental factors including a strong association with the gene for human leukocyte antigen B27. This inflammatory disorder affects ligamentous insertions into bones; at first, it usually affects the sacroiliac joints and lumbar spine. In some patients, the entire spine is involved, with ossification of the ligaments and fusion of the vertebra. The spine becomes rigid and susceptible to a variety of disorders that may affect the spinal cord, including fractures and dislocations, atlanto-occipital dislocation, and spinal stenosis.

A cauda equina syndrome may appear in patients with long-standing spondylitis. Signs and symptoms are symmetric, with weakness, wasting, and sensory loss in lumbosacral myotomes. Autonomic dysfunction and more specifically parasympathetic dysfunction may occur. Bladder and bowel are commonly affected, and pain may be severe. The mechanism is not clear. Although concomitant arachnoiditis has been suspected as the cause, the syndrome appears late, when there is little evidence that the underlying spondylitis is active. Moreover, there is little inflammation at postmortem examination, which is likely to show chronic fibrosis.

Diagnosis

There is erosion of posterior bone elements, and, in earlier days, myelography showed enlargement of the caudal sac and prominent diverticula of the arachnoid. The CT shows similar pathology, but MRI is more illuminating, showing nerve root thickening and sometimes enhancement of dura and nerve roots; that pattern suggests inflammation of the arachnoid structures, supporting the earlier theory.

Management

Surgery is generally ineffective and has sometimes been deleterious, although there have been rare reports of some relief. Steroid therapy has been similarly without benefit. Physical therapy may be useful. Studies suggest the use of nonsteroidal anti-inflammatory drugs or selective cyclooxygenase-2 inhibitors for symptomatic patients. Tumor necrosis factor inhibitors are useful for patients whose symptoms persist despite treatment with nonsteroidal anti-inflammatory drugs.

Outcome

Prognosis of ankylosing spondylitis depends on extraspinal manifestations, age at diagnosis, lifestyle, and treatment. Factors that affect quality of life include progressive structural and functional impairments. Cross-sectional studies and a meta-analysis of 38 studies in patients with ankylosing spondylitis found that patients with ankylosing spondylitis have significantly lower health-related quality of life when compared with either controls or the general population.

ATLANTOAXIAL DISLOCATION

Introduction

Atlantoaxial dislocation refers to loss of stability between the atlas and axis (C1-C2). The subluxation of C1 on C2 occurs in many conditions that render the odontoid process of C2 ineffective as a stabilizing post. Etiologies include cervical trauma, a congenital malformation (alone or in combination with other

anomalies of the cervical spine or cranium), or secondary to inflammatory diseases.

Epidemiology

Atlantoaxial dislocation is extremely rare in persons without any predisposing factors, can occur equally in men and women, and can present at any age. Atlantoaxial dislocation occurs with disproportionate frequency with Down syndrome (up to 30%), ankylosing spondylitis, and rheumatoid arthritis, particularly older patients (reported ranges between 25% and 80%).

Pathobiology

Pathobiology depends on etiology. Traumatic atlantoaxial dislocation is a result of disruption of the transverse, alar, or apical ligaments. Ligamentous laxity and osseous abnormalities among patients with Down syndrome leads to atlantoaxial dislocation. Among patients with inflammatory disorders such as rheumatoid arthritis, chronic inflammation causes laxity and stretching of the transverse ligament, development of granulation tissue, and erosion of the bony structures.

Diagnosis

Clinically, patients can present with mild axial neck pain, paresthesias, weakness, or signs of myelopathy on exam. In more advanced cases, patients may have lower cranial nerve dysfunction. Atlantoaxial dislocation can be diagnosed with either plain spine films, CT, or MRI.

Management

For symptomatic cases, surgical stabilization is indicated. For asymptomatic cases, there has to be consideration of the risks of surgery against uncertain risks of no surgery. A general recommendation is to consider stabilization or decompression if imaging shows deformation of the neuraxis, symptomatic, or not. A closed reduction and brace immobilization was successfully applied to a patient with traumatic bilateral rotatory dislocation of the atlantoaxial joints.

Outcome

If untreated, there is risk of cervical myelopathy or medullary compression and sudden death has been reported. Among symptomatic patients who are treated, prognosis is good.

FRACTURES AND SECONDARY OSTEOPOROSIS: NEUROLOGIC CAUSES

Introduction

Epilepsy, stroke, multiple sclerosis (MS), and Parkinson disease are all neurologic diseases associated with secondary osteoporosis resulting in increased risk of fracture. In addition, certain treatments of neurologic diseases including glucocorticosteroids, antiepileptic drugs (AEDs), and unfractionated heparin have an independent negative effect on bone. Steroid-induced osteoporosis is the most common cause of secondary osteoporosis. Enzyme-inducing AEDs such as phenytoin, phenobarbital, and carbamazepine are independently associated with lower bone mineral density (BMD). Vitamin D insufficiency is reported in all of these neurologic conditions contributing to reduced BMD and increased fracture risk.

Epidemiology

Fracture rates are increased approximately twofold in persons with epilepsy. Similarly, fractures occur 2 to 7 times more commonly in patients with stroke than in patients without stroke. Risk factors include stroke severity and living alone at time of stroke. Fracture rates are also higher in patients with MS and in persons with Parkinson disease. In Parkinson disease, the femur is the most commonly fractured bone, whereas in the community, it is the radius. Men with Parkinson disease seem to be at particular increased risk for hip fracture. A Korean population–based case control study also found increased risk of osteoporotic vertebral compression fracture in patients with Parkinson disease. Higher percentages of osteoporosis are found in persons with Parkinson disease.

Pathobiology

Among patients with epilepsy falls secondary to seizure activity, gait imbalance because of AED treatment, and potential direct effects of AED therapy on bone including secondary osteoporosis all contribute. After a stroke, fractures usually occur relatively late after stroke onset and more commonly affect the paretic side of the body. The tendency to fall as a result of poststroke hemiplegia and disuse osteoporosis increase the fracture risk. In MS patients, fracture risk is increased because of reduced BMD secondary to immobility, prolonged corticosteroid use, and vitamin D insufficiency. Similarly, vitamin D deficiency, a common finding among patients with Parkinson disease, and increased risk of falling contribute to risk of osteoporosis and fractures.

Diagnosis

Clinically, it is important to recognize that persons with neurologic diseases are at increased risk for secondary osteoporosis and fracture. Screening of patients at risk includes serologic 25-hydroxyvitamin D testing and BMD assessment using dual-energy x-ray absorptiometry.

Management

When necessary, vitamin D supplementation should be encouraged. For those with epilepsy taking enzyme-inducing AEDs, higher doses of vitamin D supplementation will be needed. Bisphosphonates are commonly used to slow progression of osteoporosis and reduce fracture risk. Randomized controlled trials have found an increase in BMD, a reduction in fracture when bisphosphonates were given to patients with epilepsy LEVEL 3[1] or Parkinson disease LEVEL 3,[2] and an open-label study found similar benefits among stroke survivors LEVEL 3.[3] A meta-analysis of eight randomized clinical trials including five stroke trials and three Parkinson disease trials found that there is efficacy against hip fracture with bisphosphonate treatment with stroke and Parkinson disease. No study has assessed their impact among MS patients.

Some reports suggest that bisphosphonates are associated with an increased risk of atrial fibrillation and may increase the risk of ischemic stroke. A Danish case control population-based study and an English case control study did not find an association between oral bisphosphonates and risk of ischemic stroke. Similarly, an analysis using a Danish nationwide cohort of over 100,000 patients with first time hospitalization for stroke found no evidence that preadmission bisphosphonate use increases 30-day mortality following stroke. A nonsignificant increased risk was found in association with an intravenous formulation (zoledronic acid) in an international multicenter randomized study. Interestingly, animal models suggest that bisphosphonates have an antiatherosclerotic effect, and in one population study, persons who received bisphosphonates had a lower risk of stroke when followed for a 2-year period. These results need to be followed up with a randomized clinical trial.

Outcome

Prognosis depends on identification and treatment of osteoporosis as well as implementing strategies to reduce fall risk. There are, however, limited well-designed studies demonstrating effects of interventions for preventing falls.

128 Malnutrition, Malabsorption, and Vitamin Deficiencies

Rebecca Traub and Inna Kleyman

KEY POINTS

1. Many malnutrition or malabsorption syndromes leading to neurologic complications result from multivitamin deficiency rather than a single low vitamin level.
2. Vitamin B_{12} deficiency is one of the more common vitamin deficiency syndromes and results in subacute combined degeneration of the spinal cord.
3. Thiamine deficiency, most often seen in patients with alcohol abuse or severe malnutrition states, can cause an acute Wernicke-Korsakoff syndrome or severe sensorimotor polyneuropathy.
4. In addition to vitamin deficiency, excessive consumption of some vitamins or minerals can lead to neurologic toxicity.
5. Neurologic complications of vitamin and mineral deficiency should always be considered in patients with a history of bariatric surgery.
6. Other gastrointestinal disorders affecting absorption, including inflammatory bowel disease and celiac disease, also increase risk for vitamin deficiency syndromes.
7. Celiac disease can cause various neuropsychiatric manifestations with peripheral neuropathy and ataxia being the most common.

INTRODUCTION

Malnutrition and malabsorption lead to isolated and multiple nutritional deficiencies with neurologic manifestations that are ascribed to lack of vitamins or other essential nutrients. An excess of certain vitamins or minerals may also cause neurologic syndromes. Obesity and caloric excess also contribute directly and indirectly to neurologic health status. The wide range of neurologic complications of obesity and dietary excess including ischemic stroke, diabetic neuropathy, and degenerative disease of the spine are covered elsewhere in this text. Treatments for the epidemic of obesity have also led to nutritional disorders and neurologic disease.

Although this chapter describes typical syndromes associated with specific vitamin deficiencies, it should be noted that in clinical practice, vitamin deficiency and malnutrition are often multifactorial with multiple deficiencies occurring together to lead to clinical symptoms and signs.

CAUSES OF NUTRITIONAL DEFICIENCIES

Nutritional deficiency may occur due to inadequate dietary intake or impaired absorption related to intrinsic or iatrogenic gastrointestinal disorders. In developing countries, inadequate nutritional intake is often due to inadequate access to food and natural sources of vitamins and minerals. In developed or industrialized countries, causes of impaired intake may include alcoholism, eating disorders, or other causes of severely restricted dietary intake. Alcohol abuse is a major cause of malnutrition and is associated with numerous neurologic syndromes, the pathophysiology of which may be direct toxicity of ethanol, single or multiple vitamin deficiencies, or a combination of these factors. Another common cause of malnutrition is *anorexia nervosa*. Severely reduced caloric intake related to eating disorders often causes neuropathy, myopathy, and other syndromes related to multiple vitamin deficiencies.

Malabsorption may arise for any of several reasons, both intrinsic and iatrogenic. Bowel diseases causing malabsorption include inflammatory bowel disease, celiac disease, and disorders of pancreatic enzyme function. In patients with these disorders, neurologic abnormalities seem to be disproportionately frequent. Alone or in combination, there may be evidence of myopathy, sensorimotor peripheral neuropathy, and degeneration of corticospinal tracts, posterior columns, and cerebellum. Optic neuritis, atypical pigmentary degeneration of the retina, and dementia are less common sequelae of malabsorption.

Bariatric surgery to treat obesity and its associated complications typically involves restricting gastric volume. Neurologic complications are uncommon but may be attributed to a combination of malabsorption and hyperemesis resulting in multivitamin deficiency state. Vitamin and mineral supplementation is routinely instituted after bariatric surgery to prevent such complications. Neurologic complications of bariatric surgery are discussed in more detail later in this chapter.

VITAMIN DEFICIENCY AND EXCESS SYNDROMES

Although many presentations of neurologic disorders related to malnutrition are attributed to deficiencies of multiple vitamins and minerals occurring together, there are particular syndromes and neurologic disorders that are typically described with specific deficiencies (Tables 128.1 and 128.2). Oversupplementation of

TABLE 128.1 Neurologic Syndromes Attributed to Vitamin or Mineral Deficiency

Vitamin or Mineral	Neurologic Symptoms or Signs in Deficiency
B_1 (thiamine)	Seizures (infants), Wernicke encephalopathy, Korsakoff dementia, subacute peripheral neuropathy
B_3 (niacin)	Encephalopathy, peripheral neuropathy
B_6 (pyridoxine)	Peripheral neuropathy, ataxia, altered mental status, seizures
B_9 (folate)	Neural tube defects (prenatal deficiency)
B_{12} (cobalamin)	Myeloneuropathy, cognitive impairment, optic neuropathy
A	Xerophthalmia
D	Myopathy
E	Spinocerebellar syndrome, neuropathy, myopathy, ophthalmoplegia
Copper	Myeloneuropathy
Iron	Restless legs syndrome

some vitamins or minerals may also lead to neurologic disorders. In the following sections are descriptions of some of the more commonly seen syndromes.

Vitamin B_{12} (Cobalamin) Deficiency

Pernicious anemia, caused by vitamin B_{12} deficiency, includes the triad of anemia, neurologic symptoms, and atrophy of the epithelial surface of the tongue. The term *combined degeneration of the spinal cord* to describe the nervous system consequences of vitamin B_{12} deficiency was introduced around 1900. Replacement therapy began in the 1920s with dietary liver and parenteral liver extract in 1948, the year that vitamin B_{12} was identified. Vitamin B_{12} deficiency continues to be common, with increased risk with older age related to atrophic gastritis, decreased dietary intake, and use of medications that interfere with acid secretion.

Epidemiology

The prevalence of vitamin B_{12} deficiency varies, based on the population studied. Most studies have described a prevalence of 1% in the general population and 5% in older adults. The prevalence of pernicious anemia among older adults has been reported to be 2%, with higher rates in women than in men. Rates of vitamin B_{12} deficiency are over 10% for patients following gastric surgery.

TABLE 128.2 Neurologic Syndromes Attributed to Vitamin or Mineral Excess

Vitamin or Mineral	Neurologic Symptoms and Signs in Excess States
B_6 (pyridoxine)	Neuropathy, ganglionopathy
A	Intracranial hypertension
Manganese	Parkinsonism
Selenium	Neuropathy
Zinc	Myeloneuropathy (through copper deficiency)

Pathobiology

Cobalamin is synthesized only in specific microorganisms, and animal products are the sole dietary source. Gastric acid is needed for peptic digestion to release the vitamin from proteins. The freed vitamin B_{12} is bound by R proteins and then by gastric intrinsic factor, a glycoprotein produced by gastric parietal cells, which is needed for transport of vitamin B_{12} and which is absent in people with pernicious anemia. The combined intrinsic factor–cobalamin complex is transported across the terminal ileum and binds to transcobalamin, which then enters cells for use in metabolic processes.

About 80% of adult-onset pernicious anemia is caused by lack of gastric intrinsic factor secondary to atrophic gastritis. The disorder is thought to be autoimmune in origin because antibodies to gastric parietal cells are found in 90% and antibodies to intrinsic factor occur in up to 76% of people with pernicious anemia. Pernicious anemia also coexists with other autoimmune diseases. In those with normal intrinsic factor, the vitamin is not absorbed because of jejunal diverticulosis, tropical or celiac sprue, or loss of the stomach or ileum by surgical resection. Proton pump inhibitors and H_2-blocker medications to treat gastroesophageal reflux or peptic ulcer disease can also cause vitamin B_{12} deficiency. Chronic recreational or occupational exposure to nitrous oxide can interfere with cobalamin metabolism and cause neuropathy or combined system disease. Long-term metformin therapy for diabetes mellitus can also lead to vitamin B_{12} deficiency through interference with calcium-dependent ileal membrane function.

Pathology of Vitamin B_{12} Deficiency

In the spinal cord, white matter is affected more than gray matter. Symmetric loss of myelin sheaths occurs more often than axonal loss; changes are most prominent in the posterior and lateral columns (*combined system disease or subacute combined degeneration*; Figs. 128.1 and 128.2). The thoracic cord is affected first, and then the process extends into the cervical or lumbar spinal cord. Patchy demyelination may be seen in the frontal white matter, correlating clinically with cognitive symptoms.

Diagnosis

Today, most people with vitamin B_{12} deficiency are probably asymptomatic. If the deficiency persists, symptoms may be those of anemia, neurologic disorder, or other problems such as vitiligo, sore tongue, or prematurely gray hair. About 40% of all patients with vitamin B_{12} deficiency have some neurologic symptoms or signs, and these are often the first or most prominent manifestations of the disease. Usually, there are features of both myelopathy and peripheral neuropathy. The most common symptom is acroparesthesia—burning and painful sensations that affect the hands and feet. There may be sensory ataxia due to loss of proprioception. Memory loss, visual loss (owing to optic neuropathy), orthostatic hypotension, anosmia, impaired taste (dysgeusia), sphincter dysfunction, and impotence are other symptoms and signs that have been described. Vitamin B_{12} levels should be checked in all people undergoing evaluation of cognitive impairment, as it is a treatable cause of memory loss.

The diagnosis rests on demonstration of serum levels of vitamin B_{12} under 200 pg/mL, but low-normal values (200-350 pg/mL) may be found in people who respond to therapy. Some people with low values are not deficient, and additional tests may be useful. Both methylmalonic acid and homocysteine accumulate when there is impairment of cobalamin-dependent

FIGURE 128.1 Subacute combined degeneration. Sections of spinal cord at various levels showing segmental loss of myelin, which is most intense in the dorsal and lateral columns.

reactions; both metabolites are abnormally increased in serum in more than 99% of patients with true cobalamin deficiency. There are limitations to these tests in certain populations, with elevated homocysteine in hereditary homocysteinemia and elevated methylmalonic acid in patients with renal failure. Pernicious anemia, which often underlies vitamin B_{12} deficiency, is best assessed with intrinsic factor antibodies. Sensitivity of these antibodies is only 50% to 70%, but specificity is nearly 100%. Antiparietal cell antibodies are more sensitive but less specific.

In patients with neurologic signs, only about 20% have severe anemia. Both the hematocrit and mean corpuscular volume may be normal, although anemia and macrocytosis are the classic abnormalities. Bone marrow biopsy reliably shows megaloblastic abnormalities.

Other testing in vitamin B_{12} deficiency may include magnetic resonance imaging (MRI) or electrodiagnostic testing. The MRI may show increased T2-weighted signal and contrast enhancement of the posterior and lateral columns of the spinal cord (Fig. 128.3), with return to normal following treatment. Nerve conduction tests may show an axonal sensorimotor neuropathy, although usually are normal. Vitamin B_{12} deficiency must be considered in any sensorimotor neuropathy, myelopathy, autonomic neuropathy, dementia, or optic neuropathy.

FIGURE 128.2 Subacute combined degeneration. Destruction of myelin predominating in the posterior and lateral columns. Swelling of affected myelin sheaths causes spongy appearance.

Management

Vitamin B_{12} replacement is given intramuscularly at a dosage of 1,000 μg daily for the first week, followed by weekly injections for the first month, and then monthly injections for at least a number of months. Although some patients require lifelong vitamin B_{12} injections, particularly those with pernicious anemia or surgical procedures affecting the terminal ileum, others may be transitioned to oral or sublingual formulations for maintenance therapy. There are some studies suggesting that high-dose oral vitamin B_{12} (1,000-2,000 μg daily) may even be a sufficient treatment in place of intramuscular therapy as initial treatment of deficiency.

Outcome

After injection of vitamin B_{12}, hematologic improvement may be evident within 48 hours as well as a subjective sense of general improvement. Paresthesias are often the first neurologic symptoms to improve and do so within 2 weeks; corticospinal and cognitive abnormalities are slower to respond, typically within 3 months but sometimes with continued improvement up to a year. If there is no response in 3 months, the condition is probably not from vitamin B_{12} deficiency. About half of patients are left with some neurologic abnormality on examination; the residual disability, both related to the myelopathy or cognitive injury, depends on the duration and severity of symptoms at the time that treatment is started.

Vitamin B_1 (Thiamine) Deficiency

Introduction

Thiamine is an important cofactor in the metabolism of amino acids and carbohydrates. Thiamine also plays a role in the neuromuscular junction and neurotransmission.

Epidemiology

Thiamine deficiency most often occurs as a complication of severe caloric restriction. In developing countries, this may occur as "outbreaks" in the setting of famine and among refugee populations. In developed countries, thiamine deficiency is most often seen as a complication of alcoholism, eating disorders, or after gastric surgery. The elderly may be at particular risk for thiamine deficiency due to poor absorption of the vitamin.

Pathobiology

The typical manifestations of thiamine deficiency include beriberi, both infantile and adult, and Wernicke-Korsakoff syndrome.

FIGURE 128.3 Increased T2 signal in the posterior columns on cervical spine magnetic resonance imaging in vitamin B_{12} deficiency. **A:** Sagittal. **B:** Axial. (Courtesy of Dr. Alexander G. Khandji, Professor of Radiology, Columbia University)

Infantile beriberi typically occurs in the first few months of life, with primarily a cardiopulmonary picture, although a neurologic syndrome of vomiting, nystagmus, and seizures may occur. Infants fed with formula deficient in thiamine have developed beriberi, with a cluster of cases seen in Israel in 2003. Adult beriberi has traditionally been divided into two subtypes. Dry beriberi refers to a sensorimotor neuropathy, which usually occurs with a subacute presentation. The neuropathy can be severe, causing near quadriplegia. Wet beriberi refers to the high-output heart failure sometimes accompanying the neuropathy of adult thiamine deficiency.

Wernicke-Korsakoff syndrome is a central nervous system (CNS) manifestation of thiamine deficiency. Wernicke encephalopathy refers to the acute presentation of altered mental status, ataxia, and ophthalmoplegia. This syndrome has traditionally been described in alcoholics although can be seen in anyone with malnutrition or malabsorption. Many do not have the full clinical triad and rather have isolated ataxia or ophthalmoplegia. *Korsakoff syndrome* refers to the more chronic manifestations of CNS injury due to thiamine deficiency: dementia with prominent or isolated memory deficits and confabulation.

Diagnosis

Thiamine can be measured in a number of ways, most often as a blood level. Supplementation, often given intravenously in the emergency department or ambulance, will usually invalidate tests for vitamin B_1 deficiency. The diagnosis is usually made based on historical and clinical grounds, unless a vitamin B_1 level is measured before supplementation. In Wernicke-Korsakoff syndrome, MRI of the brain may demonstrate typical abnormalities, including T2 hyperintense signal and restricted diffusion in the mamillary bodies and thalami (Fig. 128.4). These MRI findings are often reversible with treatment.

Management

Thiamine can be given intravenously or intramuscularly for deficiency conditions, typically 100 mg daily for 7 to 14 days, followed by oral supplementation. Acute Wernicke encephalopathy is treated with even higher doses, 500 mg intravenously three times daily for 3 days and then once daily for an additional 5 days. In any patient at risk for thiamine deficiency (eg, history of alcoholism or other risk factors for malnutrition), thiamine should be given in the emergency setting prior to glucose administration to avoid precipitation of acute Wernicke encephalopathy, as glucose metabolism increases demand for thiamine. Some advise prophylactic oral thiamine supplementation in alcoholics, elderly, or others at risk for deficiency.

FIGURE 128.4 Increased T2 signal in the mamillary bodies and midbrain tectum *(arrows)* in Wernicke encephalopathy due to thiamine deficiency.

Outcome

Prompt treatment with intravenous thiamine as described in the preceding text will often improve the clinical symptoms of thiamine deficiency, including peripheral neuropathy or Wernicke-Korsakoff syndrome, but patients will often have some residual disability that is not fully reversible.

Vitamin B_6 (Pyridoxine) Deficiency or Excess

Introduction

Vitamin B_6 has a number of critical cofactor roles, including metabolism of amino acids, lipids, and carbohydrates. It also plays a role in neurotransmitter formation, endocrine function through effects on steroid hormones, and in both the humoral and cell-mediated immune system.

Epidemiology

Vitamin B_6 deficiency typically occurs in combination with other vitamin deficiencies and is seen in any medical condition that causes malnutrition or malabsorption. Specific risk factors for pyridoxine deficiency include uremia and dialysis, alcoholism, older age, disorders of systemic inflammation, and human immunodeficiency virus. Certain medications may reduce vitamin B_6 levels in plasma.

Pathobiology

Vitamin B_6 Deficiency

Low vitamin B_6 levels have been associated with peripheral neuropathy, although isolated vitamin B_6 deficiency causing neuropathy is probably rare. Ataxia and altered mental status have also been reported with low levels of this vitamin. Severe vitamin B_6 deficiency leads to seizures, rarely seen from dietary deficiency. The genetic condition of pyridoxine-dependent seizures is a treatable cause of refractory epilepsy in neonates.

Vitamin B_6 Toxicity

Excessive supplementation with vitamin B_6 can cause sensory neuropathy and in severe cases, sensory ganglionopathy. Most cases are at doses of vitamin B_6 over 250 mg daily, although some have occurred at doses as low as 100 mg daily.

Diagnosis

Pyridoxine levels can be measured in plasma. A fasting specimen is the most accurate measure of vitamin B_6 tissue stores. In an individual person with neuropathy, it may be difficult to interpret a modestly elevated or reduced vitamin B_6 level and know whether it is responsible for clinical symptoms. The lab testing must be combined with clinical history and symptomatology to interpret values.

Management

Vitamin B_6 is orally supplemented in cases of deficiency at a dose of 50 to 100 mg daily.

Outcome

Vitamin B_6 supplementation in deficiency cases should improve or reverse neurologic symptoms. Pyridoxine-dependent seizures will also respond to treatment with supplementation. Patients with severe sensory neuropathy or ganglionopathy from pyridoxine toxicity will often have loss of the sensory dorsal root ganglion and may not show much clinical improvement, rather stabilization of deficits, with cessation of the vitamin supplementation.

Vitamin B_9 (Folic Acid) Deficiency

Folate is found in many vegetables, legumes, and animal products and in many fortified grains and foods. The primary neurologic role of folate supplementation is in women during pregnancy (or chance of pregnancy), where it plays a critical role in neural tube formation. Prenatal folic acid supplementation reduces the risk of neural tube defects by 50% to 70%. Supplements are recommended at least a month before conception, given that formation of the neural tube occurs during the first weeks of embryonic development. In women at low risk for neural tube defects, 0.4 to 0.8 mg daily is recommended. In those on antiepileptics that interfere with folate absorption or those with a prior history of pregnancy with neural tube defect, 4 mg daily is recommended.

In adults, folate deficiency has primarily hematologic manifestations, with rare, if any, neurologic symptoms. There is limited benefit to checking folate levels in patients presenting with dementia, neuropathy, or other neurologic syndromes. It should be noted that folic acid supplementation may mask vitamin B_{12} deficiency by correcting some of the associated anemia and allowing the associated neurologic syndrome to go undiagnosed. Therefore, vitamin B_{12} levels should be assessed before initiating folate replacement.

Vitamin B_3 (Niacin) Deficiency

Niacin deficiency (pellagra) is primarily seen in populations that are dependent on corn but can also be seen in the setting of alcoholism, malabsorption, chronic infection, carcinoid syndrome, secondary to vitamin B_6 deficiency, and in Hartnup syndrome, an autosomal recessive disorder that causes impaired synthesis of niacin from tryptophan. Pellagra typically affects the gastrointestinal tract, skin, and the nervous system (ranging from neuropsychiatric symptoms to encephalopathy that may progress to spasticity, ataxia, myoclonus, or coma). Deficiency can also cause a peripheral neuropathy similar to that seen with thiamine deficiency. Treatment with oral or intravenous nicotinic acid results in variable improvement of the neurologic manifestations.

Vitamin A Deficiency or Toxicity

Vitamin A is a fat-soluble vitamin found in plants (beta-carotene or provitamin A) and animal sources, particularly fish, dairy, and meat, especially liver (retinol, preformed vitamin A). Retinoids are compounds related to retinol, many with actions similar to vitamin A. Physiologically, vitamin A has critical roles in fetal eye development and maintenance of retinal photoreceptor cells. Vitamin A deficiency is uncommon in developed countries but remains one of the most common nutritional deficiencies worldwide. In developed countries, vitamin A deficiency may occur in disorders of fat absorption, as in cystic fibrosis, pancreatic disorders, and celiac disease.

Vitamin A deficiency causes *xerophthalmia*, a term used to describe the spectrum of eye diseases related to deficiency, from night blindness to complete blindness and dryness or ulceration of the conjunctiva and cornea. Diagnosis of vitamin A deficiency is typically made on clinical grounds, although serum retinol levels may be measured.

Vitamin A toxicity (hypervitaminosis A) may also cause neurologic disease, with a clinical presentation of increased cerebrospinal

fluid pressure similar to the syndrome of idiopathic intracranial hypertension. Most cases occur with ingestion of excessive amounts of supplements, although it has also been described in people consuming large amounts of dietary liver. Isotretinoin, a retinoic acid derivative used for the treatment of acne, can similarly cause pseudotumor cerebri, presumably through similar mechanism of action.

Vitamin D Deficiency

Vitamin D is a fat-soluble vitamin obtained through diet or skin exposure to ultraviolet rays in sunlight. Deficiency may occur due to inadequate dietary intake, disorders of fat absorption, and inadequate exposure to sunlight. The primary manifestations of vitamin D deficiency are related to bone development and maintenance, with rickets in children and osteomalacia in adults. However, vitamin D is implicated in a number of neurologic conditions. Severe vitamin D deficiency has been described causing myopathy but only at very low serum levels, typically in cases of malabsorption. Patients with epilepsy are at increased risk for low bone density and fracture. This increased risk is multifactorial and complex, partially related to cytochrome P450 enzyme–inducing antiepileptic medications, which increase vitamin D metabolism. Because of this risk of bone loss in many patients with epilepsy, vitamin D and calcium supplementation are generally advised. Vitamin D has effects on multiple cellular functions of the immune system, and studies have demonstrated an association between vitamin D deficiency and a number of autoimmune disorders, including multiple sclerosis. Whether supplementing vitamin D in patients already diagnosed with multiple sclerosis is beneficial from a clinical standpoint has yet to be established. Diagnosis of vitamin D deficiency is made by measuring 25-hydroxyvitamin D levels to assess vitamin D status. There is some variation in goal levels, with most recommending 30 to 40 ng/mL.

Vitamin E Deficiency

Vitamin E is a fat-soluble vitamin found in many foods, including meat, oil, eggs, and vegetables. It is an antioxidant and a component of cell membranes. Risk factors for vitamin E deficiency are disorders that impair fat absorption, including cholestasis and pancreatic deficiencies. There are genetic diseases causing deficient vitamin E absorption and resultant neurologic impairments. The typical neurologic manifestations of vitamin E deficiency include neuropathy, myopathy, and ataxia.

MINERAL DEFICIENCY AND EXCESS SYNDROMES

Copper Deficiency and Toxicity

Introduction

Copper, a trace mineral present in many foods, is absorbed in the stomach and proximal small intestine. In the liver, it becomes part of ceruloplasmin, which is transported through the body. Copper deficiency has multisystemic effects on skin and hair, liver, bone, and the nervous system. Risk factors for copper deficiency are malabsorption, including gastric surgery and celiac disease, and excessive zinc ingestion through supplements or zinc-containing denture creams.

Epidemiology

Risk of copper deficiency is greatest in patients with malabsorption syndromes or with a history of gastric surgery. A number of cases have been described associated with excessive zinc supplementation.

Pathobiology

The neurologic syndrome of copper deficiency is typically myelopathy or myeloneuropathy, often mimicking vitamin B_{12} deficiency. There is gait ataxia, sensory loss, and spasticity, with physical exam demonstrating prominent loss of vibration and joint position sense, hyperreflexia, and extensor plantar responses.

Diagnosis

Lab testing in copper deficiency will show a low serum copper and/or ceruloplasmin level. When excessive zinc ingestion is suspected as a cause of copper deficiency, serum zinc and 24-hour urinary zinc can be measured. Given the similar clinical features, vitamin B_{12} levels should always be checked in patients with suspected copper deficiency myeloneuropathy, and imaging of the spinal cord is often indicated, showing abnormal signal in the posterior columns.

Management

Copper is supplemented at a dose of 2 mg daily. Some recommend higher doses for initial treatment in the symptomatic patient. Usually, oral supplementation suffices; however, intravenous and intramuscular forms can be used if there is concern for severe impaired absorption.

Outcome

Improvement in myeloneuropathy symptoms typically occurs with copper supplementation and correction of deficiency state.

Wilson Disease

Wilson disease, which is described in detail in Chapter 139, is a hereditary, autosomal recessive disorder of excessive copper accumulation, which leads to liver disease and a characteristic neurologic syndrome of ataxia, dysarthria, dystonia, tremor, and parkinsonism.

Other Mineral Deficiencies and Toxicities

- Iron: Iron deficiency in childhood is associated with developmental delays. In adults, iron deficiency is a treatable cause of restless legs syndrome.
- Manganese: Manganese toxicity, primarily occurring through occupational exposure, although also reported in patients receiving parenteral nutrition, can cause symptoms similar to those seen in Parkinson disease.
- Selenium: Selenium toxicity, typically occurring in excessive supplementation, causes neuropathy in association with dermatologic symptoms.
- Zinc: Excessive zinc ingestion, as described earlier, causes a secondary copper deficiency and associated myeloneuropathy.

NEUROLOGIC COMPLICATIONS OF BARIATRIC SURGERY

Introduction

Surgical procedures performed to manage obesity are broadly referred to as *bariatric surgery*. These are increasingly common treatment options for weight reduction and improved management of hypertension, diabetes, sleep apnea, and metabolic disorders. The overall objective of bariatric surgery is to reduce intake or absorption of macronutrients (fats, carbohydrates, proteins) to reduce caloric intake, but the absorption of micronutrients (essential minerals and vitamins) is also affected. There are several different types of surgical options including gastric bypass (Roux-en-Y gastric bypass), sleeve gastrectomy, adjustable gastric band, and biliopancreatic diversion with duodenal switch (BPD/DS). Sleeve gastrectomy and band placement both reduce stomach volume and are considered restrictive procedures. Gastric bypass and BPD/DS are considered malabsorptive procedures because they impair normal digestion and absorption of food (in addition to having a restrictive effect). Although gastric bypass is considered the "gold standard" of weight loss surgery and is the most commonly performed procedure worldwide, sleeve gastrectomy has become the most common procedure performed in the United States.

Micronutrient deficiencies may occur days, months, or even many years following bariatric surgery. Some patients have underlying deficiency before undergoing surgery, and these deficiency states can be worsened postoperatively due to vomiting, reduced absorption, changes in diet and gut microbiome, and loss of intrinsic factor and gastric acid. Deficiency of vitamin B_{12}, folate, thiamine, and copper is most common following bariatric surgery, but absorption of vitamin E, pyridoxine, niacin, vitamin A, and vitamin D is also affected.

Various neurologic complications can arise from malabsorption and deficiency of these individual vitamins and nutrients. These are seen more frequently in bariatric procedures causing substantial malabsorption, such as gastric bypass and BPD/DS, and are less likely in restrictive procedures like sleeve gastrectomy and adjustable band placement. Complications such as compressive or stretch peripheral nerve injuries, rhabdomyolysis, Wernicke encephalopathy, and inflammatory polyradiculoneuropathies tend to occur in the early postoperative period, and peripheral neuropathy, myelopathy, myopathy, and optic neuropathy occur later.

Epidemiology

More than an estimated 250,000 bariatric surgeries were performed in the United States in 2018 (and an estimated 630,000 procedures performed worldwide in 2016). It has been reported that up to 9% of patients who have bariatric surgery experience neurologic complications related to micronutrient malabsorption. Peripheral neuropathy accounts for 70% to 80% of these complications with CNS involvement being the least common.

Pathobiology

The Roux-en-Y gastric bypass procedure is performed by dividing the upper portion of the stomach to create a small stomach pouch; the proximal small intestine is then divided and its distal end is connected to the stomach pouch. The remaining end of the proximal small intestine is connected to small intestine further down, where food mixes with digestive enzymes. With this type of bypass, less digestion occurs in the stomach and less absorption occurs in the small intestine. In the BPD/DS procedure, a small stomach pouch is created and a large portion of the small intestine is bypassed; there is a significant reduction in absorption because food and digestive enzymes do not mix until far down the small intestine.

Vitamin B_{12} deficiency is common in bypass procedures because most of the stomach and duodenum are bypassed, reducing the breakdown of vitamin B_{12} and its binding with intrinsic factor. As described previously in this chapter, vitamin B_{12} deficiency typically presents with paresthesias, weakness, loss of position and vibratory sense, and cognitive changes. This can take months to years to develop because haptic stores are usually sufficient to maintain levels. A less common, but more serious, complication after bariatric surgery is Wernicke encephalopathy due to thiamine deficiency. This can present as ataxia, nystagmus, and memory dysfunction. Thiamine deficiency can also be accompanied by a sensorimotor peripheral neuropathy or painful and rapidly progressive polyradiculoneuropathy. This can be seen within days to week postoperatively and is more frequent in patients with severe vomiting.

Other neurologic complications related to individual vitamin and mineral deficiencies affected by bariatric surgery are reviewed in more detail earlier in this chapter.

Diagnosis

Although there are guidelines for nutritional supplementation and management following bariatric surgery, deficiency states still occur due to issues with adherence, follow-up, hyperemesis, and preexisting nutrient deficiency. Patients should ideally be screened for vitamin and mineral deficiencies preoperatively and supplemented appropriately before undergoing surgery. Postoperatively, there are guidelines for regular follow-up and serum testing of various vitamins and minerals. It can be difficult to predict which patients will develop deficiencies, so close surveillance is essential.

Management

If a specific deficiency does develop, prompt recognition and treatment can help prevent irreversibly neurologic injury. It is generally accepted that lifelong multivitamin supplementation is necessary after bariatric surgery, but specific recommendations regarding supplements and dosing vary; this may depend on the type of procedure performed, the specific deficiency identified, and the clinical course postoperatively.

NEUROLOGIC COMPLICATIONS OF GLUTEN-RELATED DISORDERS

Introduction

Gluten-related disorders can broadly be divided into autoimmune (including celiac disease and gluten ataxia), allergic, and nonautoimmune nonallergic (gluten sensitivity). We will focus

specifically on the neurologic complications of the autoimmune subtype in this section.

Celiac disease is an autoimmune enteropathy involving the adaptive immune system, which can cause gastrointestinal symptoms like diarrhea, malabsorption, and weight loss as well as neurologic sequelae. Various neurologic manifestations have been described including peripheral neuropathy, epilepsy, headaches, increased intracranial pressure, neuromyelitis optica, stiff person syndrome, myopathy, myelopathy, myoclonus ataxia, chorea, paroxysmal nonkinesigenic dystonia, other movement disorders, and psychiatric conditions.

Epidemiology

The estimated prevalence of celiac disease in the United States is about 1%. Neurologic manifestations may appear in up to 22% of people with celiac disease, and individuals with celiac disease have an estimated 2.5-fold increased risk of developing peripheral neuropathy.

Pathobiology

The pathogenesis of neurologic complications seen in gluten-related disorder is not well understood but is thought to be immune mediated and related to gluten-triggered inflammatory changes. Celiac disease and gluten-related disorders can cause deficiencies of vitamin E, copper, vitamin B_{12}, folate, zinc, vitamin B_1, vitamin B_6, and vitamin D. However, nutritional deficiency secondary to malabsorption is not the only explanation for the spectrum of neurologic sequelae, and immune factors likely play a greater role.

Peripheral neuropathy in celiac disease typically presents as a chronic axonal sensorimotor neuropathy, but chronic inflammatory demyelinating polyradiculoneuropathy, autonomic neuropathy, mononeuritis multiplex, small fiber neuropathy, and sensory ganglionopathy have also been reported.

Gluten ataxia is a related immune-mediated disorder that refers to adult-onset progressive ataxia in the presence of gluten antibodies and is thought to be triggered by gluten ingestion in genetically susceptible individuals. Cerebellar atrophy and white matter abnormalities may be seen on MRI of the brain, and pathologic examination has shown Purkinje cell loss and lymphocytic infiltration within the cerebellum and posterior columns of the spinal cord. Gastrointestinal symptoms are not necessarily present.

Diagnosis

Affected individuals may have the presence of gliadin-related immunoglobulin A antibodies (antiendomysial and antitissue transglutaminase) along with histopathologic evidence of damage to the small intestinal mucosa (villous atrophy, crypt hyperplasia, increased epithelial lymphocytes) on biopsy. Human leukocyte antigen genetic testing and response to a gluten-free diet can also be used to help establish the diagnosis. Neurologic manifestations may be present without gastrointestinal symptoms, so it is important to consider this diagnostic possibility even without typical gastrointestinal complaints.

Management

Strict adherence to a gluten-free diet is generally effective in treating many of the neurologic complications described in the preceding text; however, the clinical response may be variable. Patients with long-standing symptoms may have some irreversibly injury. Some studies have shown a response to immunotherapy such as intravenous immunoglobulin and oral immunomodulatory agents, but this is not well established.

129 Neurologic Disease During Pregnancy

Alison M. Pack

KEY POINTS

1. Pregnancy may be associated with alterations in preexisting neurologic conditions, such as epilepsy or migraine, or herald the emergence of neurologic disorders, such as peripheral nerve entrapment or a movement disorder.
2. Pregnancy rates for women with epilepsy have increased. Most women maintain good seizure control throughout pregnancy. The majority of women with epilepsy deliver healthy babies.
3. Preeclampsia can progress to eclampsia, a syndrome of diffuse multifocal brain edema that can result in posterior reversible encephalopathy syndrome.
4. Pregnancy is a risk factor for stroke, and the postpartum period is the most vulnerable time.
5. The multiple sclerosis relapse rate decreases in pregnancy, especially in the third trimester, and increases in the first 3 months postpartum.
6. The majority of migraine headaches improve during pregnancy, especially for migraines without aura.
7. Carpal tunnel syndrome is the most frequent neuropathy of pregnancy.
8. Myasthenic symptoms in pregnancy are variable and can increase in 30% to 40% of patients. Exacerbations occur more likely in the first trimester and postpartum period.
9. Restless legs syndrome is the most common movement disorder of pregnancy.

INTRODUCTION

Pregnancy and the postpartum period are times of major biologic and social changes. Pregnancy may be associated with alterations in preexisting neurologic conditions, such as epilepsy or migraine, or herald the emergence of neurologic disorders, such as peripheral nerve entrapment or a movement disorder. This chapter addresses the diagnosis, management, and treatment of neurologic disorders arising in or altered by pregnancy.

Biology of Pregnancy

Physiologic changes during pregnancy may influence the expression of neurologic disease and complicate management. Alterations in neuroactive steroid hormones may affect the phenotypic appearance of the disease. Changes in pharmacokinetics, medication compliance, and sleep patterns may make disease management more challenging.

The concentration and type of circulating steroid hormones change during pregnancy. Estrogen production increases. In the nonpregnant state, the main circulating estrogens are estradiol, which is synthesized by ovarian thecal cells, and estrone, which is produced by the extraglandular conversion of androstenedione. Estriol is a peripheral metabolite of estrone and estradiol. In pregnancy, the concentrations of all these estrogens, particularly estriol, increase. As pregnancy progresses, maternal steroids and dehydroisoandrosterone from developing fetal adrenal glands are converted principally to estriol. Progesterone production also increases dramatically. These hormonal changes may affect neurologic conditions that are hormone responsive, including migraine, epilepsy, and multiple sclerosis (MS).

Drug pharmacokinetics is affected by the physiologic changes of pregnancy (Table 129.1). Renal blood flow and glomerular filtration increase as a function of increased cardiac output. Plasma volume, extravascular fluid, and adipose tissue increase to create a larger volume of distribution. Serum albumin decreases, which reduces drug binding, increases the free fraction, and increases drug clearance. These pharmacokinetic alterations may affect drug concentrations and are most important for drugs that are highly protein bound, hepatically metabolized, or renally cleared.

Other events of pregnancy that may compromise management are hyperemesis gravidarum, sleep deprivation, and poor compliance. Hyperemesis gravidarum can make it difficult to maintain adequate concentrations of oral medications. Sleep deprivation aggravates many neurologic conditions and can be a particular problem in the third trimester. Compliance may deteriorate because of a woman's concern that taking medication might harm her baby. Women are often advised by friends, relatives, and even medical personnel to minimize fetal drug exposure.

TABLE 129.1 Physiologic Changes During Pregnancy[a]

Variable	Change
Extracellular volume	Increases 4-6 L
Plasma volume	Increases 40%
Renal blood flow	Increases 30%-50%
Glomerular filtration rate	Increases 30%-50%
Cardiac output	Increases 30%-50%
Serum albumin	Decreases 20%-30%

[a]Data from Silberstein SD. Drug treatment and trials in women. In: Kaplan PW, ed. *Neurologic Disease in Women*. New York, NY: Demos Medical Publishing; 1998:25-44.

This may lead to skipped doses, reduced doses, or even self-discontinuation of an indicated medication.

EPILEPSY

Epidemiology

Each year, 20,000 women with epilepsy become pregnant. This number has grown as marriage rates have increased for women with epilepsy because parenting has become more socially supported and because the medical management of pregnancy in women with epilepsy has improved.

Seizure Control and Monitoring Antiseizure Medication Concentrations

Although most women do maintain good seizure control throughout pregnancy, particularly if they have been seizure free for the 9 months preceding conception, seizure frequency may change. Changes responsible for this include changes in sex hormones, antiseizure medication (ASM) metabolism, sleep schedules, and medication compliance. ASM concentrations may change. The total ASM concentration falls because of an increase in volume of distribution, decreased drug absorption, and increased drug clearance. Lamotrigine (Lamictal) concentrations decrease throughout pregnancy because of markedly increased clearance mediated by estrogen-induced increased glucuronidation. Monitoring of this medication should be performed at least monthly and appropriate adjustments made. Concentrations of levetiracetam (Keppra), oxcarbazepine (Trileptal), and topiramate (Topamax) also decrease in pregnancy and doses need to be adjusted. For some ASMs that are highly protein bound, although the total concentration decreases, the proportion of unbound or free drug increases because albumin levels and protein binding decline. Therefore, it is necessary to follow the non–protein-bound drug concentrations for ASMs that are highly protein bound, including carbamazepine (Tegretol), phenytoin sodium (Dilantin), and sodium valproate (Depakene). Dose adjustments should maintain a stable non–protein-bound fraction.

Teratogenicity

The incidence of major congenital malformations (MCMs) in association with in utero ASM exposure is increased at least two- or threefold when compared to the general population. In a pooled analysis of 26 studies, MCMs occurred at a higher rate for infants born to women with epilepsy on ASMs (6.1%) compared with women with epilepsy off ASMs (2.8%) and a control population (2.1%). Current published risks are derived from data gathered from international prospective registries. A prospective U.S.-based North American registry continues to gather information about pregnancy and fetal outcome in women using ASMs. This registry should be contacted regarding any woman who becomes pregnant while taking ASMs (1-888-233-2334). A European registry includes countries throughout Europe, Asia, and the continent of Australia and prospectively records information about the effects of ASMs as monotherapy on the developing fetus. The Australian group has independently published their findings. A U.K. register is also actively following pregnant women with epilepsy. MCMs related to ASM exposure include neural tube defects, cleft lip and palate, cardiac defects (atrial septal defect, tetralogy of Fallot, ventricular septal defect, coarctation of the aorta, patent ductus arteriosus, and pulmonary stenosis), and urogenital defects.

Data is available for many of the commonly used ASMs (Table 129.2). Among the currently available ASMs, valproate is consistently associated with the highest rate of MCMs including a higher risk of neural tube defects. Results from the European Surveillance of Congenital Anomalies found that in utero valproate exposure resulted in a 12.7-fold increase (odds ratio 12.7; 95% confidence interval [CI], 7.7-20.7) of spina bifida when compared to those with no exposure. Findings suggest the risk of valproate-associated MCMs increases at doses above

Abbreviations: EURAP, international registry of antiepileptic drugs and pregnancy; NA, not available.

[a]Reported number and percentage of major congenital malformations, 95% confidence interval (CI), and number of exposures in the EURAP Registry, North American Register, and United Kingdom and Ireland Register.

700 mg/d. Phenobarbital, which is used throughout the world, particularly in developing countries, results in a significantly increased risk of MCMs, notably cardiac malformations. First-trimester topiramate exposure is associated with an increased risk of oral clefts. Although carbamazepine has a lower total risk of MCMs than valproate, results from European Surveillance of Congenital Anomalies found a 2.6-fold increased risk of spina bifida (odds ratio, 2.6; 95% CI, 1.2-5.3) when compared to those with no exposure. Lamotrigine and levetiracetam are associated with the lowest risk. Data are limited for other commonly used ASMs including brivaracetam, eslicarbazepine, lacosamide, perampanel, and pregabalin.

Higher ASM doses are likely associated with higher risk of MCMs. The international registry of antiepileptic drugs and pregnancy (EURAP) Registry has found that the risk of MCMs increased with increasing dose at time of conception for valproate, phenobarbital, carbamazepine, and lamotrigine.

Polytherapy may an independent risk factor for teratogenicity. Rates of major malformations are elevated in children exposed to multiple ASMs. The specific ASM combination is likely a factor. For example, ASM combination therapy that includes valproate has a higher MCM rate than other ASM combinations.

Several mechanisms have been postulated to explain the teratogenicity of ASMs. Some ASMs may be teratogenic because of free radical intermediates that bind with RNA and disrupt DNA synthesis and organogenesis. Higher concentrations of oxide metabolites increase the risk of fetal malformations. Some ASMs cause folic acid deficiency, which is associated with higher occurrence and recurrence rates of neural tube defects. The American Academy of Neurology (AAN) and American Epilepsy Society recommend that all women with epilepsy of childbearing age receive at least 0.4 mg of folic acid per day. There is currently insufficient evidence to know if higher doses of folic acid offer greater benefit.

Effects of Antiseizure Medications on Cognition

In addition to the teratogenicity of ASMs, ASMs may also affect cognitive outcomes of exposed infants. Retrospective and prospective studies suggest a negative effect of valproate; children whose mothers took valproate have lower scores on neuropsychological tests and have more special needs. Early studies were limited by retrospective design, size, and inability to control for confounding variables such as maternal IQ. Data from the prospective well-controlled Neurodevelopmental Effects of Antiepileptic Drugs (NEAD) study finds that in utero, valproate exposure was associated with impaired cognitive development. Children exposed to valproate had significantly lower IQ scores at age 6 years (analyses controlled for maternal IQ, ASM dose, gestational age, and folic acid use) when compared to children whose mothers took carbamazepine, lamotrigine, or phenytoin. In addition, findings from NEAD suggest that verbal abilities may specifically be at risk from valproate as well as the other studied ASMs (carbamazepine, lamotrigine, and phenytoin). Periconceptional folic acid use resulted in improved cognitive outcomes. The mean IQs were higher in children exposed to periconceptional folic acid (mean, 108; 95% CI, 106-111) when compared to unexposed children for all ASMs (mean, 101; 95% CI, 98-104; $P = .0009$). Valproate exposure has also been reported to increase the risk of autism and autism disorders among in utero–exposed children. Cognitive outcome data is limited for other commonly used ASMs.

Management of Epilepsy During Pregnancy

Management of epilepsy in women of reproductive age should focus on maintaining effective control of seizures while minimizing fetal exposure to ASMs. This applies to dosage and number of ASMs. Medication reduction or substitution should be considered prior to conception. Altering medication during pregnancy increases the risk of breakthrough seizures and exposes the fetus to an additional ASM. The recommended ASM management in pregnancy is monotherapy at the lowest effective dose. Higher ASM doses are associated with higher risks of MCMs as well as poorer cognitive outcomes. If there is a family history of neural tube defects, an agent other than valproate and carbamazepine should be considered.

Seizures in pregnancy may result in miscarriage, preterm labor, fetal bradycardia, and injury to the mother and child. Seizures do not appear to increase the risk of MCMs. Frequent generalized tonic-clonic seizures increase risk of impaired cognitive development.

Once a woman is pregnant, prenatal diagnostic testing includes a maternal serum α-fetoprotein and an anatomic ultrasound at 14 to 18 weeks. This combination will identify more than 95% of infants with neural tube defects. In some instances, amniocentesis may be indicated.

Enzyme-inducing ASMs may result in ASM-related vitamin K deficiency, which increases the risk of early fetal hemorrhage. Although earlier AAN guidelines recommended that women taking enzyme-inducing ASMs be given supplemental vitamin K (vitamin K_1, 10 mg/d) for the last month of gestation, there is insufficient evidence to determine if prenatal vitamin K supplementation reduces neonatal hemorrhagic complications. Importantly, all neonates receive vitamin K at delivery.

For pregnant women with new-onset seizures, the diagnostic strategy is similar to that for any patient with a first-time seizure. The neurologic history and examination can be directed to signs of a specific cause, such as acute intracranial hemorrhage or central nervous system (CNS) infection. Evaluation should include screening for hypertension, proteinuria, and edema to exclude eclampsia. Follow-up studies include serologic tests for syphilis and human immunodeficiency virus, electroencephalogram (EEG), and magnetic resonance imaging (MRI), which is the preferred imaging technique for pregnant women. As in nonpregnant women with a first-time seizure, treatment depends on seizure type and cause.

Breastfeeding

The American Academy of Pediatrics recommends breastfeeding for the first 6 months of life. Although infants whose mothers take ASMs will continue to be exposed to ASMs in breast milk, findings from a prospective study, the Maternal Outcomes and Neurodevelopmental Effects of Antiepileptic Drugs supports that overall drug exposure is low. The median percentage of infant-to-mother concentration for seven commonly used ASMs (carbamazepine, levetiracetam, lamotrigine, oxcarbazepine, topiramate, valproate, and zonisamide) ranged from 0.3% to 44.2% in 164 infant-mother concentration pairs. In support of breastfeeding are findings from the NEAD study assessing and comparing cognitive outcomes in breastfed children exposed to

ASMs with nonbreastfed children (exposed to ASMs in utero). Breastfed children had a higher IQ and adjusted verbal index compared to nonbreastfed children.

PREECLAMPSIA AND ECLAMPSIA

Preeclampsia and eclampsia are most often seen in young primigravida women and in multiparous women with a change in partner. Preeclampsia is a multisystem disorder that is diagnosed clinically by hypertension, proteinuria, and edema. Modern consensus definitions define preeclampsia as pregnancy-induced hypertension beginning after 20th week with proteinuria. Women are also defined as having preeclampsia if they have pregnancy-induced hypertension without proteinuria if they have other common symptoms including cerebral symptoms, epigastric or right upper quadrant pain with nausea or vomiting, or thrombocytopenia and abnormal liver enzymes. Preeclampsia is associated with hepatic and coagulation abnormalities, hypoalbuminemia, increased urate levels, and hemoconcentration. Studies suggest that secreted antiangiogenic factors such as fms-like tyrosine kinase 1 contribute to the acute symptomatology and potential long-term effects. Women who develop preeclampsia/eclampsia should be screened for glomerular and cardiovascular disease throughout life.

Epidemiology

Preeclampsia affects 5% to 8% of pregnancies. In black women, preeclampsia has a higher prevalence and is more likely to be associated with maternal complications. Cerebrovascular disease is the leading cause of maternal mortality in women with preeclampsia. Preeclampsia can progress to eclampsia, a syndrome of diffuse multifocal brain edema that can result in posterior reversible encephalopathy syndrome. Fewer than 5% of women with preeclampsia progress to eclampsia. The incidence in Europe and other developed countries is 1 per 2,000. In developing countries, the incidence varies from 1 in 100 to 1 in 1,700. Worldwide, eclampsia probably accounts for 50,000 deaths annually.

Clinical Features

Neurologic abnormalities associated with *eclampsia* may include headaches, confusion or lethargy, seizures, cortical blindness or visual field defects, coma, brain hemorrhage, or death due to herniation from massive global cerebral edema. Seizures are most often generalized but may be focal. Common neurologic findings on exam include memory deficits, increased deep tendon reflexes, visual perception deficits, visual information–processing deficits, altered mental status, and cranial nerve deficits. Cortical blindness and visual field defects may occur because occipital lobes are preferentially involved.

Diagnosis

The differential diagnosis of eclampsia includes subarachnoid hemorrhage and cerebral venous thrombosis. The diagnosis is established by appropriate clinical features in the presence of increased blood pressure plus proteinuria, edema, or both. A significant increase in blood pressure is defined as an increase of more than 15 mm Hg diastolic or 30 mm Hg systolic above baseline measurements obtained before or early in pregnancy. If no early reading is available, a blood pressure of 140/90 mm Hg or higher in late pregnancy is significant.

FIGURE 129.1 Symmetric posterior edema on magnetic resonance imaging T2 fluid-attenuated inversion recovery images characteristic of posterior reversible encephalopathy syndrome in a hypertensive pregnant woman who presented with visual changes (patches in her vision). (From Hosley CM, McCullough LD. Acute neurological issues in pregnancy and the peripartum. *Neurohospitalist*. 2011;1:104-116.)

Neuroimaging, EEG, cerebrospinal fluid analysis, and angiography may help in diagnosis. Computed tomography (CT) is usually normal in eclampsia but may show hypodense regions in areas of cerebral edema. MRI provides better detection of edema in the cortical mantle and is the mainstay for confirming the diagnosis. MRI characteristically shows sulcal hyperintensity and small multifocal microinfarcts and hemorrhages, with a predilection for the occipital lobes (Fig. 129.1). EEG may show spike-and-wave discharges. The cerebrospinal fluid is usually normal in preeclampsia, but the protein content may be moderately elevated, and the pressure may be increased. In some patients, angiography shows arterial spasm. A subset of patients with severe eclampsia also develop hemolysis, elevated liver enzymes, and a low platelet count (HELLP) syndrome.

Pathologic examination of eclamptic brains reveals petechial hemorrhages in cortical and subcortical patches. Microscopically, these petechial hemorrhages are ring hemorrhages about capillaries and precapillaries occluded by fibrinoid material. Areas that are predisposed include the parietooccipital and occipital regions.

Treatment

The most accepted treatment of eclampsia is delivery of the fetus, if possible. Hypertension should be treated with continuous infusion antihypertensive agents, initially directed toward attaining the patient's baseline premorbid blood pressure levels or a 20% reduction in systolic blood pressure, whichever is higher. Presently, magnesium sulfate (a 4- to 6-g loading dose, followed by an infusion of 1 to 2 g an hour, with a target serum magnesium level of 2.0-3.5 mmol/L) is the first-line treatment for the prevention and treatment of eclamptic seizures and other symptoms of eclampsia. Randomized trials have compared magnesium sulfate and other agents including phenytoin and diazepam, and the

results suggest that magnesium sulfate is the agent of choice. An international randomized placebo-controlled trial (MAGnesium sulphate for Prevention of Eclampsia [MAGPIE] trial) compared the use of magnesium sulfate and placebo for preeclampsia; magnesium sulfate halved the risk of eclampsia and reduced the risk of maternal death from 1.9% to 0.8% LEVEL 1.[1] Hypertension refractory to magnesium alone can be treated with intravenous nicardipine, clevidipine, or labetalol. There were no substantive harmful effects to mother or baby in the short term. For women at high risk for preeclampsia, the U.S. Preventive Services Task Force recommends low-dose aspirin as preventive medication after 12 weeks of gestation LEVEL 1.[2]

STROKE

Epidemiology

Pregnancy is a risk factor for stroke, and the postpartum period is the most vulnerable time. Stroke incidence as determined in a systematic review and meta-analysis is 30.0 per 100,000 pregnancies with a mean age of 22 to 33 years. When compared to nonpregnant young adult age groups, the incidence is 3 times higher. Using the National Inpatient Sample, acute stroke occurred in 1 of every 2,222 hospitalizations with no decrease in over 9 years. Factors that increase the risk (**Table 129.3**) for stroke include pregnancy-related hypertension and cesarean delivery. Certain medical conditions may also increase the risk. Data from the National Inpatient Sample of the Healthcare Cost and Utilization Project suggest that the incidence of pregnancy-associated stroke has risen since the 1990s. The analysis, which included all types of pregnancy-associated strokes, found a 47% increase when comparing the time periods 1994-1995 to 2006-2007. Concurrent hypertensive disorders and heart disease explain most of the increase. Among those with acute stroke in the National Inpatient Sample analysis, there were increases in prevalence of most stroke risk factors including obesity, smoking, hyperlipidemia, migraine, and gestational hypertension increased. Mortality is approximately 10% to 13% and is higher in black women, older women, and those with no prenatal care. Presumptive mechanisms include changes in the coagulation and fibrinolytic systems leading to a hypercoagulable state and an increase in viscosity and stasis, which can promote thrombosis. In the postpartum period, the large decrease in blood volume at childbirth, rapid changes in hormone status that alter hemodynamics and coagulation, and the strain of delivery may predispose to a stroke. The risk of thrombosis in the postpartum period persists until at least 12 weeks after delivery.

TABLE 129.3 Risk Factors for Maternal Stroke

Older age
African American race
Obesity
Hypertensive disorders of pregnancy Gestational hypertension Preeclampsia Eclampsia
Cardiac disease Preexisting chronic hypertension Preexisting valvular, congenital, or ischemic heart disease
Cesarean delivery
Infections
Migraines
Diabetes
Hematologic disorders Sickle cell disease Antiphospholipid syndrome Thrombotic thrombocytopenic purpura Hyperhomocysteinemia Mutations in prothrombin gene Deficiencies in antithrombin III, protein C, protein S, and factor V Leiden
Systemic lupus erythematosus
Smoking
Alcohol use
Recreational drug use (particularly cocaine)

Ischemic Stroke

Arterial occlusion resulting in cerebral infarction (see Chapter 36) accounts for approximately one-half of strokes in pregnant women and occurs primarily in the second and third trimesters. Arterial strokes are generally a consequence of identifiable risk factors, including premature atherosclerosis, moyamoya disease, Takayasu arteritis, fibromuscular dysplasia, and primary CNS vasculitis.

Cerebral Venous Thrombosis

Cerebral venous thrombosis (see Chapter 41) is the second most common cause of stroke in pregnant women, causing approximately one-third of strokes in pregnant women. Cerebral venous thrombosis usually occurs late in pregnancy or in the postpartum period. The pathophysiology of venous infarctions differs from strokes associated with arterial occlusion because they occur in the setting of venous thrombosis secondary to venous congestion and rise in pressure. A systematic review and pooled analysis of pregnancy-related cerebral venous thrombosis found the most frequently involved sinuses are the superior sagittal sinus (67%) and the transverse sinus (64%). Contributing factors include the underlying hypercoagulable state in pregnancy, alterations in platelet function, prothrombotic and antithrombotic proteins, as well as iron deficiency anemia and adaptive response to hemorrhage of labor and delivery. Testing for free protein S deficiency, an acquired hypercoagulable state, is positive in many patients. The clinical presentation is variable because the woman can present with headaches (the most common presenting symptom), focal neurologic deficits, depressed mental status, or seizures. Hematologic disorders can play an etiologic role in arterial and venous strokes (see **Table 129.3**). Other causes are cardiogenic and paradoxic emboli.

Diagnosis

The key to early diagnosis of stroke in pregnancy is prompt neuroimaging. As with nonpregnant patients, CT and MRI should be done to identify areas of stroke as well as study cerebral vasculature. MRI is the preferred imaging modality in pregnancy, and scanning is safe in all trimesters; no human data demonstrates increased teratogenicity. In the emergent evaluation of stroke, CT may be more readily available. The estimated fetal radiation exposure for a single maternal CT of the head is far below safety threshold for

teratogenesis or developmental disabilities. Angiography including magnetic resonance, CT, or transfemoral catheter angiography may be needed to assess stroke etiology. The current gold standard for diagnosing cerebral venous thrombosis is magnetic resonance venography in combination with MRI. Imaging of cerebral venous thrombosis reveals thrombus within cerebral vein or venous sinus either without parenchymal changes or with evidence of cerebral edema, apparent ischemic stroke, or hemorrhage. Hemorrhage occurs in almost half of those with cerebral venous thrombosis (see "Cerebral Hemorrhage" section for further discussion). Further evaluation such as cardiac ultrasound and serologic studies to evaluate for conditions associated with an increased stroke risk should be pursued. With the exception of protein C, protein S, and antithrombin III deficiency, other hypercoagulable studies can be performed. Evaluation of protein C, protein S, and antithrombin III factors should occur at least 6 weeks after delivery because they are directly affected by pregnancy itself.

Treatment

Treatment of strokes in pregnancy is directed to the specific cause.

Intravenous Thrombolysis

Thrombolysis improves outcomes after stroke. As pregnant women were excluded from the trials involving recombinant tissue plasminogen activator, no controlled studies are available. Intravenous tissue plasminogen activator has a short half-life and does not cross the placenta, and there is a shift to consider its use in pregnancy. Studies find comparable outcomes of pregnant or postpartum women when compared to nonpregnant women. Potential concern relates to maternal hemorrhage, placental hemorrhage and abruption, fetal loss, and preterm labor and not increased teratogenicity.

Mechanical Thrombectomy

Similar to intravenous thrombolysis, pregnant women were excluded from randomized thrombectomy trials. There are, however, multiple reports of pregnant women undergoing successful thrombectomy and a registry-based study found similar outcomes for pregnant women when compared to nonpregnant women.

Unfractionated and Low Molecular Weight Heparin

Anticoagulation is a treatment option for prevention of recurrent stroke in patients with stroke due to arterial dissection. Unfractionated heparin does not cross the placenta. However, long-term use (>1 mo) is associated with osteoporosis and thrombocytopenia. Use of low molecular weight heparin (LMWH) is thus considered to be a more preferable choice than unfractionated heparin because the development of osteoporosis, thrombocytopenia, as well as allergies is less likely. Indeed, LMWH is the drug of choice for treatment of venous thromboembolism from deep vein thrombosis, one of the leading causes of maternal mortality and morbidity in the developed world. Warfarin (Coumadin) crosses the placenta and is a known teratogen. It is therefore recommended only for women who cannot tolerate heparin or who have recurrent thromboembolic events. Aspirin complications in pregnancy include teratogenic effects and bleeding in the neonate. However, low-dose aspirin (<150 mg) is safe in the second and third trimesters, with no increase in maternal or neonatal adverse effects.

Anticoagulation is also the treatment of choice for cerebral venous thrombosis including those with cerebral hemorrhage. Acutely, early anticoagulation with either unfractionated heparin or LMWH is recommended. Studies find that among nonpregnant patients, patients who received heparin had lower mortality when compared to those who did not. In one study, no worsening with anticoagulation occurred in those with hemorrhage. Prolonged anticoagulation is also recommended, typically for 3 to 6 months. Warfarin can be used in the postpartum period. In those cases of cerebral venous thrombosis during pregnancy, LMWH is used and is held during labor and delivery.

CEREBRAL HEMORRHAGE

Epidemiology

The risk of cerebral hemorrhage increases in pregnancy. Cerebral hemorrhage occurs in 1 to 5 pregnancies per 10,000, with an associated mortality of 30% to 40%. Factors that predispose to hemorrhage include physiologic changes of pregnancy such as hypertension; high concentrations of estrogens causing arterial dilation; and increases in cardiac output, blood volume, and venous pressure. Pregnancy-related conditions also increase the risk of hemorrhage. These include eclampsia, metastatic choriocarcinoma, cerebral emboli, and coagulopathies.

Subarachnoid hemorrhage accounts for 50% of all intracranial bleeding in pregnancy and carries a high mortality. Cerebral aneurysms and arteriovenous malformations cause most subarachnoid hemorrhages in pregnancy. Other causes include eclampsia, cocaine use, coagulopathies, ectopic endometriosis, moyamoya disease, and choriocarcinoma. Aneurysmal bleeding usually occurs in older patients in the second and third trimesters. In contrast, hemorrhages from arteriovenous malformations occur in younger women throughout gestation, with the highest risk during labor and the puerperium. A recent large study from China did not, however, find an increased risk of hemorrhage in patients with cerebral arteriovenous malformation during pregnancy and the puerperium.

As discussed previously, cerebral venous thrombosis may also result in cerebral bleeding as a complication of venous infarction. Stasis of flow leads to infarction and secondary hemorrhage. The hemorrhage can extend to multiple areas of the brain including subarachnoid, subdural, and intraventricular spaces.

Diagnosis and Treatment

The diagnosis and treatment of subarachnoid hemorrhage and intracerebral hemorrhage in pregnant women are similar to those in nonpregnant patients. Subarachnoid hemorrhage is diagnosed by clinical manifestations and CT. If brain CT is normal and the clinical signs are consistent with intracranial hemorrhage, lumbar puncture should be performed. Once intracranial hemorrhage is detected, follow-up studies include MRI and four-vessel angiography. Noncontrast CT is also the most sensitive means of diagnosing intracerebral hemorrhage. As previously discussed, cerebral venous thrombosis is best initially diagnosed using magnetic resonance venography in combination with MRI. Digital subtraction angiography with careful venography may be necessary in equivocal cases but is less preferable due to fetal exposure to radiation. Treatment of these conditions is directed to supporting the mother and fetus and preventing complications. Blood pressure should be carefully monitored, and fetal monitoring is indicated. The specific treatment depends on the etiology of the hemorrhage and may require emergent surgery,

especially in setting of aneurysmal subarachnoid hemorrhage, when the risk of early rebleeding is high. As in nonpregnant patients, management of intracranial pressure (ICP) is important. Current practice suggests that monitoring ICP and cerebral perfusion pressure plays a role in guiding therapy in cerebral hemorrhage, particularly for patients at high risk for developing hydrocephalus.

MULTIPLE SCLEROSIS

Epidemiology

MS affects 1 in 10,000 people in Western countries, primarily women in the childbearing years between the ages of 20 and 40. MS is classified as either relapsing remitting or chronic progressive with the majority having the relapsing remitting subtype. Pregnancy is common among women with MS and the prevalence is increasing. Between approximately one-fifth and one-third of women with MS will deliver a child after disease onset. A retrospective U.S. administrative claims study using data from January 1, 2006, to June 30, 2015, found that pregnancies increased from 7.9% to 9.5% Interestingly in a similar time frame, pregnancies decreased in women without MS. Initial presentation of MS during pregnancy is unusual.

Clinical Features

Whether pregnancy affects MS onset remains inconclusive. Most published studies support either a beneficial effect or net-neutral effect, and a few studies conclude that pregnancy increases risk of developing MS. Prospective studies and other surveys found that the relapse rate decreases in pregnancy, especially in the third trimester, and increases in the first 3 months postpartum. Pregnancy, however, does not reduce relapse risk in women who stop the disease-modifying drugs fingolimod and natalizumab. Women who stop these disease-modifying drugs are at risk for severe relapse after drug cessation. Severe rebound relapses during pregnancy have been reported as early as 1 month after stopping fingolimod and 3 to 4 months after stopping natalizumab. A high relapse rate or disability before pregnancy is associated with an increased risk of postpartum attacks. Pregnancy does not increase risk of long-term disability. The outcome of the pregnancy itself is not affected by MS.

Pathobiology

The mechanisms responsible for the change in the rate of relapses include humoral and immunologic changes, as seen also in pregnant women with other autoimmune diseases such as rheumatoid arthritis or systemic lupus erythematosus. There is no correlation of relapse rate with the physical stress of childbirth and caring for the newborn, sleep deprivation, type and dose of anesthesia, breastfeeding, or socioeconomic factors.

Treatment

Treatment of MS is divided into three categories: disease-modifying, acute, and symptomatic therapies. Disease-modifying therapies include natalizumab, interferon β, glatiramer acetate, fingolimod, dimethyl fumarate, teriflunomide, ocrelizumab/rituximab, and alemtuzumab and have variable effects in pregnancy (**Table 129.4**). Although not as effective as some of the other disease-modifying agents, glatiramer acetate and interferon β are considered the safest. Teriflunomide is U.S. Food and Drug Administration (FDA) category X because it is teratogenic in animal models but there is no data to support increased teratogenicity in humans. The use of disease-modulating therapies during pregnancy should be limited to cases whereby potential benefits outweigh the risks. If a severe relapse does occur with pregnancy, a short course of corticosteroid therapy is recommended. Use in early pregnancy should be avoided if possible because it may increase the risk of oral clefts and lower birth weight. In addition, neonatal adrenal suppression may follow maternal corticosteroid use, and large prenatal doses in animals caused growth retardation and compromised development of the CNS. Symptomatic therapies should be minimized in pregnancy. Intrathecal baclofen may be safe for the treatment of severe spasticity due to MS.

TABLE 129.4 Multiple Sclerosis Disease-Modifying Therapies Effects in Pregnancy

Disease-Modifying Therapy	Effects in Pregnancy
Glatiramer acetate/ interferon β	No data of teratogenicity in animal studies Does not cross placenta No reported effects on fertility or miscarriage No reported increased teratogenicity Safe with early first trimester exposure
Dimethyl fumarate	High doses results in adverse effects in rats No increased fetal abnormalities in humans No washout period required
Teriflunomide	Increased teratogenicity in multiple animal studies No reported increased teratogenicity in human U.S. Food and Drug Administration category
Fingolimod	Probable increased teratogenicity Two-month washout period required
Natalizumab	Infant pancytopenia when given in third trimester
Rituximab/ Ocrelizumab	Infant B-cell depletion with second and third trimester exposure
Alemtuzumab	Increased embryo lethality and reduced levels of B and T lymphocytes in animal studies High risk of autoimmune thyroiditis for 4 years after stopping—may induce transient neonatal Graves disease

MIGRAINE

Epidemiology

Migraine is diagnosed in 18% of women of childbearing years. Postpartum headaches are common, occurring in approximately 30% of women typically during 3 to 6 days postpartum. They are associated with both personal and family histories of migraine headaches.

Clinical Features

Sixty percent to 70% of migraine headaches improve during pregnancy, especially for migraines without aura. Women who had migraine onset at menarche or who have had menstrual migraines are more likely to experience improvement, especially in the first or second trimester.

A Danish population-based registry study of over 22,000 pregnancies among women with migraine and over 228,000 found that women with migraine and their offspring had greater risks of several adverse pregnancy outcomes than women without migraine. Migraine was associated with an increased prevalence of low birth weight (adjusted prevalence ratio [aPR], 1.14; 95% CI, 1.06-1.23), preterm birth (aPR, 1.21; 95% CI, 1.13-1.30), and cesarean delivery (aPR, 1.20; 95% CI, 1.15-1.25) but not of small for gestational age offspring (aPR, 0.94; 95% CI, 0.88-0.99) and birth defects (aPR, 1.01; 95% CI, 0.93-1.09).

Pathobiology

Higher levels of estrogen are probably responsible for this improvement during pregnancy. The subsequent fall in estrogen levels may cause postpartum headaches.

Diagnosis

Migraines may also arise during pregnancy. Studies suggest these headaches are more likely to be with aura. If migraine arises in pregnancy, the differential diagnosis must be considered. A new-onset migraine with aura can be a symptom of vasculitis, brain tumor, or occipital arteriovenous malformation. Subarachnoid hemorrhage can cause headache any time during pregnancy or delivery. Other disorders with headache include stroke, cerebral venous thrombosis, eclampsia, pituitary tumor, and choriocarcinoma.

Treatment

Medication use during pregnancy should be limited. Nonpharmacologic approaches including biofeedback and relaxation practices have good evidence for efficacy as preventative treatments and may also be effective as an acute treatment. Acetaminophen is the analgesic of choice because studies confirm that it is safe at therapeutic doses of 4 g or less per day. If necessary, codeine or other narcotics may be used. Chronic use though can result in neonatal withdrawal. Low-dose aspirin may also be given but should be avoided toward the end of pregnancy because of increased risk of prolonged labor, postpartum hemorrhage, and neonatal bleeding. Ibuprofen is the nonsteroidal anti-inflammatory drug (NSAID) of choice during pregnancy and can be given in the first and second trimesters. Both aspirin and NSAIDs are associated with premature closure of the fetal ductus arteriosus. NSAIDs are also associated with an increased risk of oligohydramnios. Antiemetics such as metoclopramide or prochlorperazine may relieve the headache and associated nausea and vomiting. These agents are generally safe and effective. Ergotamine and dihydroergotamine mesylate (D.H.E. 45) should be avoided. The triptans are effective and widely used for the treatment of headache. Current evidence does not support adverse outcomes associated with their use in pregnancy. However, because limited information is available, their use in pregnancy is not recommended. Sumatriptan has been available the longest and is the most widely used, particularly in the first trimester. Current data suggest that first-trimester exposure of sumatriptan is not associated with any significant increase in congenital malformations or poor pregnancy outcomes. For someone with recurrent headaches, a β-adrenergic blocker, such as propranolol, may be used prophylactically. However, adverse effects including intrauterine growth retardation have been reported with β-adrenergic blockers. In addition, treatment should be stopped 2 to 3 days before delivery to reduce risk of fetal bradycardia and reduction in uterine contraction. Other agents used to prophylactically treat migraine headaches include valproate and topiramate. These agents should be discontinued prior to conception because they are both associated with higher than expected rates of MCMs. In conclusion, the choice of medication for migraine in pregnant women should balance the mother's comfort with the least fetal risk.

NEOPLASMS

Epidemiology

Brain tumors rarely become symptomatic during pregnancy. The incidence of glioma, the most common tumor in pregnancy, is 2.6 to 15 per 100,000. Systemic cancer and brain metastases are unusual in young women and rarely begin during pregnancy.

Clinical Features and Diagnosis

The types of tumors arising in pregnancy differ from those in nonpregnant women. Glioma is the most common, followed by meningioma, acoustic neuroma, and then a variety of other tumors, including pituitary tumors. Tumor growth may be exacerbated by pregnancy, especially meningioma. Possible mechanisms include increased blood volume, fluid retention, and stimulation of tumor growth by hormones.

Choriocarcinoma is the only systemic tumor specifically associated with pregnancy. Brain metastases are common in choriocarcinoma; among patients diagnosed with choriocarcinoma, 3% to 20% have brain disease at diagnosis.

Cerebral neoplasms cause headaches, seizures, focal signs, or symptoms of increased ICP. The seizures may be focal or generalized. Nausea and vomiting in the first trimester can be confused with morning sickness.

All women suspected of having a brain tumor should be examined with MRI.

Treatment

Studies suggest that pregnancy is not a contraindication to biopsy and/or resection. Radiation therapy should be avoided. Chemotherapy is definitely contraindicated. Cesarean delivery is preferable to vaginal delivery to avoid increased ICP secondary to Valsalva.

NEUROPATHIES

Women are at an increased risk for peripheral neuropathy during pregnancy and the puerperium. Backache and poorly localized paresthesias are common. At least 50% of pregnant women have back pain. Among the specific rare neuropathies that occur with a higher incidence during pregnancy are carpal tunnel syndrome, facial nerve palsy, meralgia paresthetica, and chronic inflammatory demyelinating polyneuropathy.

Carpal Tunnel Syndrome

Carpal tunnel syndrome is the most frequent neuropathy of pregnancy. Estimated prevalence ranges from 1% to 62%. A recently published prospective study reported 34% prevalence of carpal tunnel symptoms among 639 women. It usually begins in the

third trimester and disappears after delivery. It is attributed to generalized edema. Other potential hypotheses include the effect of hormones such as relaxin on ligamentous laxity, changes in sleep position, and increased adipose tissue. A prospective study found that 30% of women noted resolution of symptoms soon after delivery, 11% during lactation, and 5% after interruption of lactation. Prognosis was better for those who developed symptoms later in pregnancy.

Bell Palsy

Bell palsy appears with a slightly higher frequency during pregnancy, mostly in the third trimester. Prognosis for recovery is excellent and is similar to that in nonpregnant women. Corticosteroid use within 3 to 7 days of presentation is the current treatment recommendations for the general population. Steroids are FDA category C and are probably safe in pregnancy. The potential risks in pregnancy particularly if the woman has poorly controlled hypertension or hyperglycemia need to be considered. The AAN guidelines do not find conclusive evidence to support use of antiviral agents; they are, however, safe in pregnancy. Because studies suggest that women who develop Bell palsy have an increased incidence of hypertension and preeclampsia, these women should be monitored closely.

Meralgia Paresthetica

Meralgia paresthetica, a sensory neuropathy of the lateral femoral cutaneous nerve of the thigh, is attributed to compression of the nerve under the lateral part of the inguinal ligament. Swelling during pregnancy, increased body weight, and increased lordosis during pregnancy are possible causes. Numbness, burning, tingling, or pain in the lateral thigh suggests the diagnosis. A local anesthetic with or without steroids is usually all that is necessary. Most women improve in the postpartum period. The incidence of chronic inflammatory demyelinating polyneuropathy is slightly higher during pregnancy. As in nonpregnant women, treatment includes plasma exchange, intravenous immunoglobulin, or steroids.

MYASTHENIA GRAVIS

Epidemiology

Myasthenia gravis (MG) is 2 times more common in women than men. In women, the onset is most common in the third decade.

Clinical Features

MG symptoms are variable and reported to worsen in 30% to 40% of patients. Exacerbations occur more likely in the first trimester and postpartum period.

The total rate of pregnancy complications particularly preterm rupture of the amniotic membranes is higher among women with MG than in the general population. An association between MG and preeclampsia has been described. Pregnancy does not affect the long-term outcome of MG.

Neonatal MG affects 12% to 20% of infants born to mothers with MG. The occurrence of neonatal MG does not correlate with maternal disease severity or titer of maternal anticholinesterase receptor antibodies. The symptoms clear within a few weeks.

Treatment

Treatment of myasthenia during pregnancy includes immunosuppressant drugs, plasma exchange, and intravenous immunoglobulin. For women who develop preeclampsia and eclampsia, use of magnesium should be avoided because magnesium blocks entry at the nerve terminal and inhibits acetylcholine release. Use of prednisone in the first trimester is associated with a small increase in cleft palate, and high doses may lead to premature rupture of membrane. Use of cyclosporine is not recommended because of reported increased risk of spontaneous abortions, prematurity, and low birth weight. Rituximab is also not recommended because it is associated with B-cell lymphocytopenia. Azathioprine and mycophenolate mofetil should not be used because they can result in significant risk to the fetus and are designated by the FDA as category D, positive evidence of human fetal risk. Anticholinesterase drugs are reportedly safe. Intravenous immunoglobulin is recommended for treatment of myasthenic crisis during pregnancy. Although plasma exchange is an option for treatment of a myasthenic crisis, there is a risk of hypotension. Thymectomy is deferred until long after delivery. (Myasthenia is also discussed in Chapter 93.)

MOVEMENT DISORDERS

Movement disorders are unusual in young women, but those that specifically occur during pregnancy include the restless legs syndrome, chorea, and drug-induced movement disorders.

Restless Legs Syndrome

The restless legs syndrome is the most common movement disorder of pregnancy. It is a chronic condition that has an autosomal dominant pattern of inheritance and is characterized by a crawling, burning, or aching sensation in the calves with an irresistible urge to move the legs. It occurs in 10% to 20% of pregnant women. A systematic review and meta-analysis found a pooled overall prevalence of 21%. Symptoms can occur for the first time in pregnancy, usually in the second and third trimesters. For women with preexisting restless legs syndrome, there can be a worsening of symptoms. In a study of 606 pregnant women, 59 had preexisting restless legs syndrome and among those women, 36 reported worsening of symptoms. Iron deficiency has been found in patients with restless legs syndrome, and treatment of iron deficiency in pregnant women has been advocated, but therapeutic trials have yet not been performed. Also, lower folate levels are associated with the restless legs syndrome and treatment recommendations include folate supplementation. Other treatments include massage, flexion and extension, walking, benzodiazepines, opiates, or levodopa.

Chorea Gravidarum

Chorea gravidarum occurs in pregnancy (see Chapter 84). Treatment is reserved for those with violent and disabling chorea and includes haloperidol or benzodiazepines.

Parkinsonism and Idiopathic Parkinson Disease

Drugs that block dopamine receptors are often used to treat the nausea and vomiting of pregnancy. These drugs can cause new-onset

chorea, tremor, dystonia, or parkinsonism. Idiopathic Parkinson disease is uncommon in women younger than 40 years. More common is secondary parkinsonism caused by medication or toxins. There is no definite evidence that Parkinson disease worsens during pregnancy, and there is little information about the toxicity of antiparkinson medications. Successful pregnancies have been reported in women taking levodopa.

130 Neurologic Complications of Organ Transplantation

Eelco F. M. Wijdicks

KEY POINTS

1. Neurologic complications have declined but remain prevalent. Drug toxicity must be a common consideration.
2. Immunosuppressed transplant recipients have a proclivity for infections with *Listeria monocytogenes*, *Nocardia*, or *Aspergillus*.
3. Human herpes virus 6 (HHV-6B) is often reactivated in a graft-versus-host disease and may cause a serious form of encephalitis.
4. Progressive multifocal leukoencephalopathy remains a major late complication in transplant patients.

INTRODUCTION

Organ transplantation has been associated with a distinct spectrum of neurologic complications. Complications can emerge during pretransplant preparation (eg, hematopoietic stem cell transplantation and chemotherapy), perioperative support (eg, cardiac transplantation with cardiopulmonary bypass or extracorporeal membrane oxygenation), and postoperative management (eg, newly introduced immunosuppression). Some neurologic complications, particularly peripheral nerve injury, are related to the surgical procedure.

When large series are reported, neurologic complications from organ transplantation occur in approximately 5% to 10% of patients. Of course, the prevalence depends on the motivation of transplant teams to consult a neurologist and thus is a reflection of how relevant a neurologic complication is when seen in the whole of the clinical picture. Prospective incidence studies may not capture all the postoperative neurologic events if they are not systematically examined by neurologists. Moreover, over the years, there has been a continuous decline in neurologic complications in some types of organ transplantation, mostly as a result of increased experience with titrating immunosuppressive drugs (eg, renal, liver) and presence of skilled multidisciplinary teams. Many patients leave the intensive care unit soon after surgery.

Neurologic complications are major when they involve recurrent seizures, postoperative failure to awaken, immunosuppression neurotoxicity, or acute disabling neuromuscular disease. Familiarity with the administration and dosing of the main intravenous immunosuppressive drugs has reduced the risk of major neurotoxicity, and extreme cases with coma and seizures and neuroimaging showing diffuse white matter edema are now rarely seen.

This chapter does not attempt to fully discuss all neurologic complications described over the years and many involve the general risks of patients being immunocompromised patients. These are the most common considerations when asked to see these patients in consultation (Table 130.1).

TABLE 130.1 Neurologic Syndromes in Transplant Recipients and Causes

Failure to awaken or acute coma	Hypoxic-ischemic brain injury, brain edema, oversedation, acute graft failure, calcineurin neurotoxicity, cefepime toxicity, intracranial hemorrhage, fulminant CNS infection
Seizures	Calcineurin neurotoxicity, intracranial hemorrhage, new mass (abscess, tumor), posterior reversible encephalopathy syndrome
Aphasia, dysarthria	Calcineurin neurotoxicity, ischemic stroke
Hemiparesis	Brachial plexopathy, ischemic or hemorrhagic stroke, brain tumor, brain abscess
Tremors	Calcineurin neurotoxicity
Myoclonus, asterixis	Acute liver, renal, or pulmonary disease; drug toxicity

Abbreviation: CNS, central nervous system.

GENERAL CONSIDERATIONS

Generally speaking, and not surprisingly, a patient with more elaborate surgery has a higher risk of an early neurologic complication. For instance, liver transplantation carries a much higher risk of early neurologic complications than renal transplantation. Once the patient goes successfully through the first critical weeks, a later phase includes a proclivity for central nervous system (CNS) infections, and much later—although it may be only a few months—serious malignancies may appear. Dramatic is the appearance of posttransplant lymphoproliferative disease and likely explained from introducing genetic material of an Epstein-Barr virus (EBV)-seropositive donor into an EBV-seronegative recipient. It may involve the CNS.

Neurologic complications may result in an increased risk of early demise. Most instructively—when reviewed in more detail—the majority of patients with a lung transplantation were found to have a neurologic manifestation or complication with a third seriously affecting quality of life or resulting in a fatal outcome. That leaves the question of whether neurologic complications are sufficiently recognized.

There are several other considerations. First, neurologic complications may be specific to the type of transplantation. Neurologic complications associated with bone marrow transplantation are quite different than those from organ transplants such as a kidney or liver. Second, seizures are often drug related and less commonly due to a permanent structural lesion. It is a difficult

task to implicate certain drugs, but several drugs lower the seizure threshold (ie, calcineurin inhibitors and antibiotics such as imipenem). Third, any structural lesion in the brain, whether it has the appearance of a cerebritis or ring enhancing, is most often due to an infectious cause and requires immediate treatment. Fourth, major sodium abnormalities and osmotic shifts can be seen after liver transplantation causing osmotic demyelination.

Central Nervous System Infections

The threshold for cerebral fluid examination should be low even if meningitis is not suspected. Because an infectious mass lesion may be present, a computed tomography (CT) scan may need to be performed to exclude such a lesion. An acutely febrile patient with an abnormal level of consciousness should prompt an aggressive search for a CNS infection. Immunosuppressed transplant recipients have a proclivity for infections with *Listeria monocytogenes*, *Nocardia*, or *Aspergillus*. Infections with *Cryptococcus neoformans* or *Toxoplasma gondii* are rarely seen within 6 months after transplantation. All of these infections present often with meningeal enhancement on a CT or magnetic resonance imaging scan, solitary or multiple abscesses, or ring lesions. None of them are specific and can only be documented by biopsy. Disseminated viral infections have also been described with very high mortality rates, but again, no systemic studies have been reported.

A viral encephalopathy which has emerged more recently is a human herpes virus 6 (HHV-6B) and may become apparent with the development of acute graft-versus-host disease. The HHV-6B (but not HHV-6A) reactivation is frequent after transplantation and observed in 40% of patients. The encephalitis may have appeared already several weeks after transplantation and is not likely recognized or initially misdiagnosed as metabolic derangement or neurotoxicity from immunosuppressive agents. Delirium may be the only clinical sign before a patient lapses into a deeper coma. Isolation by polymerase chain reaction in cerebrospinal fluid is necessary. The mortality is high with about 80% of the patients remaining comatose. In any patient with a suspicion of encephalitis and without another clear cause, early empiric treatment for HHV-6B should be started with ganciclovir 5 mg/kg intravenously every 12 hours or foscarnet 90 mg/kg intravenously every 12 hours.

Another underrecognized infection is cytomegalovirus (CMV) encephalopathy. Approximately 80% of liver recipients have reactivation of a latent CMV that may occur several weeks after transplantation. Again, the diagnosis of CMV encephalitis is notoriously difficult with a presentation that is baffling to most clinicians. Some patients present with focal findings such as dysarthria, spasticity, and rigidity and tremor, and others only develop fever and neck stiffness. The CMV chorioretinitis may be demonstrated, but CMV encephalitis may occur without this manifestation. In all these opportunistic infections, recent availability of polymerase chain reaction technology has increased recognition, but there is yet no evidence that early treatment improves outcome.

Encephalopathy and Delirium

In actuality, there are particular syndromes that most often present to the neurologist. The most commonly encountered reason for a consultation has to do with assessment of an "altered state of consciousness." The appearance of a new encephalopathy may be due to rejection causing dysfunction of the graft or may have other causes.

Acute confusional state or delirium remains difficult to define in transplant recipients and can be considered if it lasts more than 2 to 3 consecutive days. Postoperative hyperactive delirium associated with hallucinations is common posttransplantation, and some circumstances should be recognized. If patients are seen in the immediate postoperative period, both hyperactive and hypoactive delirium after liver transplantation occurs in about a third of the patients. This is more often in patients who had a pretransplant encephalopathy and is more often seen in alcoholic liver disease.

In evaluating patients with impaired consciousness, some guidance can be provided. All potential sedative drugs should be carefully scrutinized, and the time remaining to clearance should be calculated. Physicians should consider administration of flumazenil or naloxone to eliminate the remaining effects. Neurotoxicity of immunosuppressive drugs is frequently implicated, and it continues to be a concern to be dealt with. None of these drugs do cause other structural disease other than a leukoencephalopathy, which cannot be clinically or radiographically distinguished from posterior reversible encephalopathy syndrome (see also Chapter 44).

Drug Toxicity

There are many drugs and medications that need to be considered in acute confusion. This includes the use of calcineurin inhibitors, opioid antagonists, β-adrenergic blockers, and high-dose corticosteroids. All of these drugs can be implicated. Other commonly used drugs, such as midazolam and propofol, may impact level of consciousness, particularly because they have different pharmacokinetics in transplant patients. Midazolam, for example, although relatively short acting in comparison with other sedative agents, has a prolonged activity if the liver graft is not functioning fully. It is also highly protein bound, and preexisting low protein levels may increase its sedative effects. Clearance of propofol is dependent on hepatic blood flow and cardiac output; and if both are disturbed, awakening from propofol may be markedly delayed, and the patient may not characteristically awaken as usually anticipated 10 to 15 minutes after discontinuation of infusion. Opioids may continue to linger after cardiac transplantation; typically, very large doses are used during the procedure.

Neurotoxicity associated with cyclosporine or tacrolimus is often considered but less often diagnosed. Breakdown of the blood-brain barrier is needed for cyclosporine to enter because no lipoprotein transport system exists. Cyclosporine is very lipophilic from aliphatic groups but cannot cross the blood-brain barrier because of tight junctions. How crossing occurs remains unknown, and perhaps, impairment of the blood-brain barrier is facilitated by surgery-associated ischemic insults due to hypotension. The predilection of the posterior areas of the brain may also be related to a less-developed blood-brain barrier that quickly opens when challenged. Oligodendroglia is more susceptible than astrocytes and explains largely white matter lesions on magnetic resonance imaging (Fig. 130.1).

The pathway of neurotoxicity associated with cyclosporine or tacrolimus has not been resolved at a molecular level. Both immunosuppressive drugs bind to an immunophilin, a protein with an affinity for both drugs, and consequently trigger a cascade of actions that include blockade of calcineurin. Calcineurin is involved in cell signaling and maintenance of cytoskeletal protein function, particularly in oligodendrocytes. Inhibition of

FIGURE 130.1 Magnetic resonance images of tacrolimus-associated toxicity with posterior white matter edema and an intraparenchymal hematoma following donor allogeneic stem cell transplant.

calcineurin activity, therefore, may lead to neuronal death or apoptosis. It remains very likely, however, that extremely high doses in the earlier days of transplantation due to unfamiliarity with the drugs has been the major driving factor. This possibility is also supported by the very low incidence of cyclosporine neurotoxicity using oral preparations, resulting in stable blood levels and avoidance of extreme blood levels during intravenous loading. The earliest abnormality seems to be neurotoxicity from fluid extravasation (vasogenic edema) and not cell destruction (cytotoxic edema). Very limited pathology studies are available, and some have suggested demyelination. Neurotoxicity is best considered a cerebral arterial leak syndrome.

One should obtain serum levels of cyclosporine or tacrolimus and trend the values. A marked increase in levels may indicate development of neurotoxicity, but such an association is only plausible if it is seen outside of the usual intravenous loading period that is within the first week of treatment. Many transplant surgeons titrate toward increasing plasma levels, and these levels should not be misinterpreted as indicative of neurotoxicity. Recent laboratory values should be obtained and should include electrolyte panel, liver and renal function tests, serum ammonia, arterial blood gas, and, where indicated, antiepileptic drug levels. Drug interactions are common with these drugs and may lead to sudden toxicity.

Finally, a mistake is to label postoperative encephalopathy as multifactorial, and it often does nothing to find the possible triggers. For example, a liver transplant recipient may have severe hyponatremia and rising creatinine and blood urea nitrogen and show signs of early rejection. Cefepime toxicity may be the cause of decline in consciousness and new myoclonus. Improvement can be expected when the drug is discontinued.

ORGAN-SPECIFIC COMPLICATIONS

Lung Transplantation

Lung transplant patients, due to significant challenges in oxygenation, may have severe neurologic complications in a third of the patients. Most severe complications are perioperative stroke and encephalopathy, and when neurologic complications occur, there is a higher mortality. Acute hyperammonemia—an unexpected and not completely explained metabolic derangement in lung transplant recipients—has also been described causing seizures and profound encephalopathy. Cyclosporin neurotoxicity is not a major cause of complications in lung transplant recipients.

Cardiac Transplantation

Cardiac transplantations are obviously at risk of ischemic injury as a result of embolization from aortic atheroembolism but also perioperative cardiogenic shock requiring extreme measures such as intra-aortic balloon pump support or extracorporeal membrane oxygenation. Intracerebral hemorrhage is rarely seen after cardiac transplantation, but poorly controlled hypertension may cause a lobar or basal ganglia hemorrhage.

Liver Transplantation

One relatively uncommon but dramatic clinical scenario is a patient with acute fulminant hepatic failure (FHF) followed by rapid listing for liver transplantation. This condition is very unique with many clinical uncertainties, and neurologists and neurosurgeons are often asked to be part of rapidly changing clinical decisions making. There are three immediate concerns. First, the transition of hepatic encephalopathy (basically a metabolic injury) to brain edema (now a structural injury) must be recognized. Second, intracranial pressure (ICP) may rise steeply and requires prompt treatment. Third, some patients may have already progressed to brain death, which would preclude transplantation.

The mechanism of brain edema in an FHF (see also Chapter 119) is influenced by multiple factors. Hyperosmolarity due to increased ammonia and also the development of oxidative stress may contribute. Brain edema is mostly vasogenic and is usually first confirmed by the appearance of severe brain swelling on CT. A useful method to identify the development of vasogenic brain edema in encephalopathic patients with FHF is to identify increased cerebral blood flow velocity associated with reduced waveform pulsatility on transcranial Doppler (see Chapter 24).

Once identified, brain edema requires aggressive treatment to prevent transtentorial herniation and is best guided by an ICP monitor (see Chapter 107). However, patients who have an ICP monitoring device placed and are treated aggressively

FIGURE 130.2 Magnetic resonance images of progressive multifocal leukoencephalopathy after liver transplantation.

do not have a better outcome or higher percentage of liver transplantation and that could question the role of ICP-based management. Most centers place an intraparenchymal ICP in comatose patients with evidence of cerebral edema on CT, but the situation is further complicated by the presence of coagulopathy, which invariably complicated FHF. Use of recombinant factor VII (4-mg intravenous push) or prothrombin complex concentrate (25-50 U/kg, depending on baseline international normalized ratio) is an important new development in countering coagulopathy in FHF. Their use has significantly decreased the frequency of bleeding complications, particularly related to ICP monitor insertion.

Intestinal Transplantation

Intestinal transplantation for a short bowel syndrome due to thrombosis, inflammatory bowel disease, and radiation enteritis has become another "organ" that can be transplanted, but experience is only in a few hundred patients. The initial experience is not sufficient to potentially identify specific complications, and most reported are in the known categories such as encephalopathy, CNS infection, seizures, stroke, and neuromuscular complications. Early assessment suggests rate of neurologic complications is much higher than solid organ transplants. One possible explanation is the higher immunosuppression as a result of relative lower resistance to rejection of the intestine. Moreover, later serious vitamin deficiencies may occur as a result of a short bowel syndrome.

LONG-TERM EFFECTS OF IMMUNOSUPPRESSION

Any transplant recipient is at risk of developing B-cell lymphomas or glioblastoma multiforme or progressive multifocal leukoencephalopathy. These disorders are extremely uncommon but can present within months after transplantation. Most notorious is the occurrence of CNS lymphoma several weeks after transplantation (may vary from a few weeks to more than two decades after transplantation). Most posttransplantation lymphomas are monoclonal B-cell lymphomas, but multiclonal B-cell lymphomas or T-cell lymphomas have been reported. The EBV infection has been linked to B-cell lymphoma. The CNS lymphoma debuts with both brain and spinal cord involvement, but presentation is nonspecific with new behavioral changes, visual hallucinations, or focal signs such as hemiparesis. In most patients, a change in personality may be the only key sign. Meningeal involvement may produce headache. The diagnosis can only be considered if the CT scan shows a new mass lesion in the periventricular region and with proportionally large amount of perilesional edema. A biopsy might be necessary to find the lesion followed by aggressive treatment with radiation. Outcome, however, remains very poor with ultimate demise in all patients.

Progressive multifocal leukoencephalopathy is caused by JC virus (see also Chapter 68), and the disorder is usually relentless (Fig. 130.2). Withdrawal of immunotherapy or highly active antiretroviral treatment is considered with some good outcomes reported.

CONCLUSIONS

There are early and late neurologic complications after organ transplantation. The nature of neurologic complications may change with new treatment protocols and new drug approaches. Neurotoxicity from immunosuppressive drugs remains commonly implicated but is not common except if the dosing is high or some new drug interaction occurs. Many patients remain subject to a number of CNS sedatives commonly used in intensive care settings. Other complications relate to common operative stressors (hypotension) or perioperative concerns (infections, hemorrhage). This field—neurology of organ transplantation—requires special expertise and frequent reassessment of the spectrum of complications.

Alcoholism 131

John C. M. Brust

KEY POINTS

1. Neurological disorders in alcoholics can be the result of intoxication, withdrawal, or other neurological complications of heavy drinking.
2. Wernicke-Korsakoff syndrome is the result of thiamine deficiency.
3. Alcoholic polyneuropathy, cerebellar ataxia, amblyopia, and dementia are probably the result of both ethanol toxicity and nutritional deficiency.
4. Although controversial, epidemiological evidence suggests that compared to abstention, mild-to-moderate ethanol intake decreases the risk of ischemic stroke whereas heavy intake increases risk of hemorrhagic stroke.
5. No threshold of safety has been identified for alcohol intake during pregnancy and the risk of fetal alcohol spectrum disorder.

INTRODUCTION

In the United States, 7% of all adults and 19% of adolescents are "problem drinkers": psychically or physically dependent on ethanol or, even if abstinent most of the time, likely to get into trouble when they drink. Ethanol-related deaths exceed 100,000 each year, accounting for 5% of all deaths in the United States. The devastation is direct (from intoxication and withdrawal) or indirect (from nutritional deficiency or other ethanol-related diseases).

ACUTE ETHANOL SYNDROMES

Intoxication

Ethanol acts at many levels of the neuraxis. Although specific ethanol receptors comparable to opioid receptors do not appear to exist, ethanol interacts directly with membrane proteins of a number of neurotransmitter systems, and much of its actions depend on facilitation at inhibitory γ-aminobutyric acid (GABA) receptors and inhibition at excitatory glutamate receptors.

Most estimates of a "standard drink" refer to 12 oz of beer, 5 oz of wine, or 1.5 oz of 80 proof spirits, each of which contains roughly 14 g of 100% ethanol. To obtain a mildly intoxicating blood ethanol concentration (BEC) of 100 mg/dL, a 70-kg person must drink about 50 g (2 oz) of 100% ethanol. Following zero-order kinetics, ethanol is metabolized at about 70 to 150 mg/kg of body weight per hour, with a fall in BEC of 10 to 25 mg/dL/h. Thus, most adults require 6 hours to metabolize a 50-g dose, and the ingestion of only 8 g of additional ethanol per hour would maintain the BEC at 100 mg/dL.

Globally, ethanol use is the seventh leading risk factor for all-cause death and disability, and it is the leading risk factor for death and disability among men and women aged 15 to 49 years. In that age group, the three leading causes of attributable death are tuberculosis, road injuries, and self-harm. Among those aged 50 years and older, the leading attributable cause is cancer.

Symptoms and signs of acute ethanol intoxication are a result of cerebral depression, possibly at first of the reticular formation with cerebral disinhibition and later of the cerebral cortex itself. Manifestations depend not only on the BEC but also on the rate of climb and the person's tolerance, which is related less to increased metabolism than to poorly understood adaptive changes in the brain. At any BEC, intoxication is more severe when the level is rising than when it is falling, when the level is reached rapidly, and when the level has only recently been achieved. A single BEC determination therefore is not a reliable indicator of drunkenness, and the correlations of Table 131.1 are broad generalizations. Death from respiratory paralysis may occur with a BEC of 400 mg/dL, and survival may occur at 700 mg/dL; a level of 500 mg/dL would be fatal in 50% of individuals.

Low to moderate BECs cause slow saccadic eye movements and interrupted jerky pursuit movements that may impair visual acuity. Esophoria and exophoria cause diplopia. With a BEC of 150 to 250 mg/dL, there is increased electroencephalography (EEG) beta activity ("beta buzz"); higher BECs cause EEG slowing. During sleep, suppression of the rapid eye movement stage is followed by rapid eye movement rebound after a few hours.

TABLE 131.1 Correlation of Symptoms With Blood Ethanol Concentration

BEC	Symptoms
50-150 mg/dL	• Euphoria or dysphoria, shyness or expansiveness, friendliness or argumentativeness • Impaired concentration, judgment, and sexual inhibitions
150-250 mg/dL	• Slurred speech and ataxic gait, diplopia, nausea, tachycardia, drowsiness, or labile mood with sudden bursts of anger or antisocial acts
300 mg/dL	• Stupor alternating with combativeness or incoherent speech, heavy breathing, vomiting
400 mg/dL	• Coma
500 mg/dL	• Respiratory paralysis

Abbreviation: BEC, blood ethanol concentration.

The term *pathologic intoxication* refers to sudden extreme excitement with irrational or violent behavior after even small doses of ethanol. Episodes are said to last for minutes or hours, followed by sleep and, on awakening, amnesia for the events that took place. Delusions, hallucinations, and homicide may occur during bouts of pathologic intoxication. Some cases might be psychological dissociative reactions; others may be owing to the kind of paradoxic excitation that sometimes follows barbiturate administration. These syndromes are more likely to occur in younger people who have had little prior exposure to alcohol.

The term *alcoholic blackout* refers to amnesia for periods of intoxication, sometimes lasting several hours, even though consciousness at the time did not seem to be disturbed. Although sometimes considered a sign of physiologic dependence, blackouts also occur in occasional drinkers. The amnesia is a direct effect of ethanol on memory encoding.

Acute ethanol poisoning causes more than 1,000 deaths each year in the United States. In stuporous alcoholic patients, subdural hematoma, meningitis, and hypoglycemia are important diagnostic considerations, but it is equally important to remember that ethanol intoxication alone can be fatal.

Blood ethanol causes a rise of blood osmolality, about 22 mOsm/L for every 100 mg/dL of ethanol; however, there are no transmembrane shifts of water, and the hyperosmolarity does not cause symptoms. Ethanol overdose should be considered in any comatose patient whose serum osmolarity is higher than predicted by calculation of the sum of serum sodium, glucose, and urea.

Patients stuporous or comatose from ethanol intoxication are generally managed similarly to those poisoned by other depressant drugs (**Table 131.2**). Death comes from respiratory depression, and mechanical ventilation in an intensive care unit is the mainstay of treatment. Hypovolemia, acid-base or electrolyte imbalance, and abnormal temperature require attention, and if there is any uncertainty about the blood glucose level, 50% glucose is given intravenously, along with parenteral thiamine. Because ethanol is rapidly absorbed, gastric lavage does not help unless other drugs have been ingested. In obstreperous or violent patients, sedatives (including benzodiazepines and dopamine-blocking agents) should be used with caution because they may push patients into stupor and respiratory depression. Patients being addressed may appear alert but then lapse into stupor or coma when stimuli are decreased.

TABLE 131.2 Treatment of Acute Ethanol Intoxication

For Obstreperous or Violent Patients
• Isolation, calming environment, and reassurance—avoid sedatives
• Close observation
• Lorazepam 2-4 mg IVP, repeated as needed, titrated to effect (calm, cooperative)
For Stuporous or Comatose Patients
• If hypoventilation, mechanical ventilation in an intensive care unit
• If hypoglycemic, intravenous 50% glucose with parenteral thiamine 100 mg
• Careful monitoring of blood pressure; correction of hypovolemia or acid-base imbalance
• Avoid emetics or gastric lavage.
• Avoid stimulants
• Do not forget other possible causes of coma in an alcoholic.

In a nonhabitual drinker, a BEC of 400 mg/dL can take 20 hours to return to zero. The only practical agent that might accelerate ethanol metabolism and elimination is fructose, but this causes gastrointestinal upset, lactic acidosis, and osmotic diuresis. Hemodialysis or peritoneal dialysis can be used for BECs greater than 600 mg/dL; for severe acidosis; for concurrent ingestion of methanol, ethylene glycol, or other dialyzable drugs; or for severely intoxicated children. Analeptic agents such as ethamivan, caffeine, or amphetamine have no useful role and can cause seizures and cardiac arrhythmia. Although patients are often depleted of magnesium, administration of magnesium sulfate may further depress the sensorium in intoxicated patients. Anecdotal reports describe temporary reversal of ethanol intoxication with the μ-opioid antagonist naloxone.

Ethanol-Drug Interactions

The combination of ethanol with other drugs, often in suicide attempts, causes 2,500 deaths annually in the United States. Ethanol is often taken with marijuana, barbiturates, opioids, cocaine, hallucinogens, and inhalants—with varying interactions. Alcoholics often abuse barbiturates, and although ethanol and barbiturates are cross-tolerant, each lowers the lethal dose of the other when they are taken in combination.

Impaired judgment and respiratory depression are also hazards when ethanol is combined with hypnotics, such as methaqualone (Quaalude), sedating antihistamines, antipsychotic agents, and benzodiazepines. Hypnotic drugs with long half-lives may cause potentially dangerous incoordination when ethanol is consumed the following day.

The cross-tolerance of ethanol with general anesthetics raises the threshold to sleep induction, but synergistic interaction then increases the depth and length of the anesthetic stage reached. Tricyclic antidepressants do not have a consistent effect; desipramine antagonizes the effects of ethanol and amitriptyline potentiates them. Ethanol and morphine, repeatedly used, can increase each other's potency, and methadone addicts not only frequently become alcoholic but also then develop a characteristic encephalopathy. Death has followed ethanol taken with propoxyphene. A mild reaction resembling that caused by disulfiram occurs when patients combine ethanol with sulfonylureas such as tolbutamide or with some antibiotics, including chloramphenicol, griseofulvin, isoniazid, metronidazole, and quinacrine.

Ethanol Withdrawal

The term *hangover* refers to the headache, nausea, vomiting, malaise, nervousness, tremulousness, and sweating that can occur in anyone after brief but excessive drinking. Hangover does not imply ethanol dependence, but *ethanol withdrawal* does imply dependence and encompasses several disorders (**Table 131.3**), which may occur

TABLE 131.3 Ethanol Withdrawal Syndromes

Early (<48 h After Last Drink)
Tremulousness
Hallucinosis
Seizures
Late (>48 h After Last Drink)
Delirium tremens

alone or in combination after reduction or cessation of drinking. Severity depends on the length and degree of a particular binge. Withdrawal syndromes are particularly common during hospitalization and can be exacerbated by concurrent illness.

Clinical Manifestations

Tremulousness

Tremulousness, the most common ethanol withdrawal symptom, usually appears in the morning after several days of drinking. It is usually promptly relieved by ethanol, but if drinking cannot continue, tremor becomes more intense, with insomnia, easy startling, agitation, facial and conjunctival flushing, sweating, anorexia, nausea, retching, weakness, tachypnea, tachycardia, and systolic hypertension. Except for inattentiveness and inability to fully recall the events that occurred during the binge, mentation is usually intact. In some patients, tremulousness can persist for weeks or longer.

Perceptual Disturbances

Perceptual disturbances, with variable insight, occur in about 25% of ethanol-dependent patients in acute withdrawal and include nightmares, illusions, and hallucinations, which are most often visual but may be auditory, tactile, olfactory, or a combination of these. Imagery includes insects, animals, or people. Hallucinations are usually fragmentary, lasting minutes at a time for several days. Sometimes, however, auditory hallucinations of threatening content last much longer and may even progress to a persistent state of auditory hallucinosis with paranoid delusions requiring care in a mental hospital. Repeated bouts of acute auditory hallucinosis may predispose to the chronic form.

Seizures

Ethanol can precipitate *seizures* in any epileptic; seizures usually occur the morning after weekend or even single-day drinking rather than during inebriation. Alcohol-related seizures affecting alcoholics not otherwise epileptic have traditionally been considered a withdrawal phenomenon, usually occurring within 48 hours of the last drink in persons who have abused ethanol chronically or in binges for months or years. The minimal duration of drinking sufficient to cause seizures is uncertain, but the risk is dose-related, beginning at only 50-g absolute ethanol daily. Seizures usually occur singly or in a brief cluster; status epilepticus is infrequent. Focal features are present in 25% and do not consistently correlate with evidence of previous head injury or other structural cerebral pathology. Alcohol seizures sometimes accompany tremulousness or hallucinosis, but they may occur in otherwise asymptomatic individuals. Their frequent appearance during active drinking or after more than 1 week of abstinence is consistent with mechanisms other than withdrawal per se.

The diagnosis of alcohol-related seizures depends on an accurate history and exclusion of other cerebral lesions. Workup should include brain computed tomography or magnetic resonance imaging and consideration of lumbar puncture. Alcohol withdrawal can trigger new-onset seizures in patients with intracranial hemorrhage, central nervous system infection, or brain neoplasm. Fewer than 10% of patients with alcohol-related seizures have spontaneous EEG abnormalities, compared with 50% of those with idiopathic epilepsy.

Transient *parkinsonism* during alcohol withdrawal is described in older patients. Transient chorea and dystonia are described in younger patients.

Delirium Tremens

In contrast to tremor, hallucinosis, or seizures, which usually occur within 48 hours of abstinence, *delirium tremens* usually begins from 48 to 72 hours after the last drink. Patients with delirium tremens are often hospitalized for other reasons. Delirium tremens may follow withdrawal seizures either before the postictal period has cleared or after 1 or 2 asymptomatic days, but when seizures occur during a bout of delirium tremens, some other diagnosis (eg, meningitis) should be considered.

Symptoms of delirium tremens typically begin and end abruptly, lasting from hours to a few days. There may be alternating periods of confusion and lucidity. Infrequently, relapses may prolong the disorder for a few weeks. Patients are typically agitated, inattentive, and grossly tremulous, with fever, tachycardia, and profuse sweating. They pick at the bed clothes or stare wildly about and intermittently shout at or try to fend off hallucinated people or objects. Hypokinetic delirium is infrequent. Mortality is as high as 15%; death is usually owing to other diseases (eg, pneumonia or cirrhosis), but it may be attributed to unexplained shock or lack of response to therapy or have no apparent cause.

Pathobiology

The pathophysiologic basis of ethanol withdrawal in its several forms is probably a combination of glutamate receptor upregulation and GABA receptor downregulation. Neuronal excitotoxicity during withdrawal could then set the stage for a kindling pattern of repeated withdrawal episodes, further excitotoxicity, a permanently lowered seizure threshold, and the occurrence of seizures temporally independent of withdrawal.

Management

Treatment of ethanol withdrawal includes prevention or reduction of early symptoms, prevention of delirium tremens, and management of delirium tremens after it starts (Table 131.4).

TABLE 131.4 Treatment of Ethanol Withdrawal

Prevention or Reduction of Early Symptoms
• Lorazepam 1-4 mg orally or IV; diazepam 5-20 mg; or chlordiazepoxide 25-100 mg repeated hourly until sedation or mild intoxication; successive daily doses tapered with resumption of higher dose if withdrawal symptoms recur
• Thiamine 100 mg and multivitamins IM or IV
• Magnesium, potassium, and calcium replacement as needed
Delirium Tremens
• Lorazepam 2-4 mg IV or IM or diazepam 10 mg IV, repeated every 5-15 min until calming; maintenance dose every 1-4 h as needed
• If refractory to benzodiazepines, phenobarbital 260 mg IV repeated in 30 min as needed
• If refractory to phenobarbital, propofol 25-100 μg/kg/min, with endotracheal intubation and repeated doses to produce general anesthesia
• Careful attention to fluid and electrolyte balance; several liters of saline per day, or even pressors, may be needed.
• Cooling blanket for high fever
• Prevent or correct hypoglycemia.
• Thiamine and multivitamin replacement
• Consider coexisting illness (eg, liver failure, pancreatitis, meningitis, subdural hematoma).

Abbreviations: IM, intramuscularly; IV, intravenously.

Benzodiazepines

Benzodiazepines, which have cross-tolerance with ethanol, are appropriately given to recently abstinent alcoholics or those with mild early withdrawal symptoms. Lorazepam (Ativan) 2 to 4 mg every 4 hours is a reasonable starting agent and dose. It is important to adjust the dose to symptom response, level of consciousness, and respiratory status after initiating therapy. A loading dose may cause symptoms of mild intoxication (calming, dysarthria, ataxia, fine nystagmus); dosage can then be adjusted to avoid both intoxication and tremulousness, and after 1 or 2 days, it can be gradually tapered, with reinstitution should withdrawal symptoms reappear.

Compared to fixed dose schedules, symptom-triggered pharmacotherapy more effectively decreases the likelihood of progression to delirium tremens and is less likely to result in sedative accumulation. Among standard protocols for symptom-triggered therapy, the Clinical Institute for Withdrawal Assessment for Alcohol (CIWA) scale assesses at regular intervals vital signs, nausea/vomiting, tremor, paroxysmal sweating, anxiety, agitation, tactile, visual or auditory disturbances, headache, and orientation/clouding of consciousness.

Anti-Adenergic Agents

β-Adrenergic blockers such as propranolol and α_2 agonists such as clonidine or dexmedetomidine are helpful as adjunctive therapy to help control symptoms of sympathetic overdrive, but they are not cross-tolerant with alcohol and have reportedly triggered hallucinosis. Phenobarbital, which has a different GABAergic mechanism of action than benzodiazepines, has also been used as add-on treatment.

Anticonvulsants

Numerous anticonvulsants, especially those with GABAergic actions, have been subjected to randomized trials comparing them to benzodiazepine or placebo for treating acute alcohol withdrawal. A Cochrane review of 56 such trials concluded that evidence was insufficient to recommend their use. Similar conclusions were reached in Cochrane reviews of baclofen or γ-hydroxybutyric acid compared to benzodiazepines in the treatment of alcohol withdrawal.

Parenteral lorazepam given to patients following an ethanol withdrawal seizure reduces the likelihood of recurrence. Status epilepticus during ethanol withdrawal is treated as in other situations. Long-term anticonvulsants are not indicated in patients whose seizures occur only during withdrawal; abstainers do not need them, and drinkers do not take them. Alcoholics whose seizures occur independent of withdrawal and epileptics whose seizures are exacerbated by ethanol unfortunately do need anticonvulsant prophylaxis even though compliance is unlikely.

Ethanol and Antipsychotics

Intravenous parenteral ethanol solutions have been used to treat delirium tremens. Treating with parenteral ethanol has the disadvantage of a low therapeutic index, and because ethanol is directly toxic to many organs, it should be avoided during hospitalization, even though most patients resume drinking on discharge. Haloperidol and phenothiazines are less likely to prevent hallucinosis or delirium tremens than drugs cross-tolerant with ethanol, and they can lower seizure threshold, prolong the QT interval, cause hypotension, and impair thermoregulation. They are appropriately considered in patients whose only symptoms are hallucinations or in whom hallucinations have outlasted other withdrawal symptoms.

General Medical Management

Hypomagnesemia is common during early ethanol withdrawal, and although it may not be the primary cause of symptoms, magnesium sulfate should be given to hypomagnesemic patients. Hypokalemia and hypocalcemia may also be present, and the latter may respond to treatment only when hypomagnesemia is corrected. Parenteral thiamine and multivitamins are given even if there are no clinical signs of depletion.

Delirium tremens, once it appears, cannot be abruptly reversed by any agent, and the mainstay of treatment is a parenteral benzodiazepine in dosage sufficient to produce adequate sedation. The required doses might be fatal in a normal person (see Table 131.4), but one cannot predict in any individual patient how high the tolerable dose is. Liver disease decreases the metabolism of benzodiazepines, and patients with cirrhosis are more vulnerable to the depressant effects of sedatives; as delirium tremens clears, hepatic encephalopathy can take its place.

General medical management in delirium tremens is intensive. Although dehydration may be severe enough to cause shock, patients with liver damage may retain sodium and water. Hypokalemia can cause cardiac arrhythmias. Hypoglycemia may be masked, as may other serious coexisting illnesses, such as alcoholic hepatitis, pancreatitis, meningitis, or subdural hematoma.

CHRONIC ETHANOL SYNDROMES

Wernicke-Korsakoff Syndrome

Clinical Manifestations

Although they share the same pathology, Wernicke and Korsakoff syndromes are clinically distinct. Wernicke syndrome, when full-blown, consists of mental, eye movement, and gait abnormalities. Korsakoff syndrome is a mental disorder that differs qualitatively from Wernicke syndrome (Table 131.5). Both are the result of thiamine deficiency.

TABLE 131.5 Major Nutritional Disturbances in Alcoholics

Disorder	Clinical Disorder	Deficiency
Wernicke syndrome	Dementia with lethargy, inattentiveness, apathy, and amnesia Ophthalmoparesis Gait ataxia	Thiamine
Korsakoff syndrome	Dementia, mainly amnesia, with or without confabulation	Thiamine
Cerebellar degeneration	Gait ataxia; limb coordination relatively preserved	Probably thiamine plus other vitamins plus ethanol neurotoxicity
Polyneuropathy	Distal limb sensory loss and weakness; less often autonomic dysfunction	Probably thiamine plus other vitamins plus ethanol neurotoxicity
Amblyopia	Optic atrophy, decreased visual acuity, central scotomas; total blindness rare	Probably thiamine plus other vitamins plus ethanol neurotoxicity

Wernicke Syndrome

In acute Wernicke syndrome, mental symptoms most often consist of a global confusional state that appears over days or weeks; there is inattentiveness, indifference, decreased spontaneous speech, disorientation, impaired memory, and lethargy. Selective amnesia is unusual. Disordered perception is common; a patient might identify the hospital room as his or her apartment or a bar. In fewer than 10%, mentation is normal.

Abnormal eye movements include nystagmus (horizontal with or without vertical or rotatory components), lateral rectus palsy (bilateral but usually asymmetric), and conjugate gaze palsy (horizontal with or without vertical), progressing to complete external ophthalmoplegia. Although sluggishness of pupillary reaction is common, total loss of reactivity to light and ptosis are rare. Mental symptoms, including progression to coma, can occur without evident abnormal eye movements in patients with pathologically verified acute Wernicke syndrome.

Truncal ataxia, present in more than 80% of patients, may prevent standing or walking. Dysarthria and limb ataxia, especially in the arms, are infrequent. Peripheral neuropathy, which occurs to some degree in most patients, may cause weakness sufficient to mask the ataxia. Abnormalities of vestibular caloric testing are common, with gradual improvement, often incomplete, over several months.

Patients with the Wernicke syndrome frequently have signs of nutritional deficiency (eg, skin changes, tongue redness, cheilosis) or liver disease. Autonomic signs are common. Although beriberi heart disease is rare, acute tachycardia, dyspnea on exertion, and postural hypotension unexplained by hypovolemia are common, and sudden circulatory collapse may follow mild exertion. Hypothermia is less frequent; fever usually indicates infection.

In acute Wernicke syndrome, the EEG may show diffuse slowing or it may be normal. Cerebrospinal fluid is normal except for occasional mild protein elevation. Elevated blood pyruvate, falling with treatment, is not specific. Decreased blood transketolase (which requires thiamine pyrophosphate as cofactor) and serum thiamine level may be depressed, but in most centers, the diagnosis depends on history and examination (and thiamine and multivitamins should be given to any alcoholic patient, symptomatic or not).

Korsakoff Syndrome

In most patients, the more purely amnestic syndrome of Korsakoff emerges as the other mental symptoms of Wernicke syndrome respond to treatment. How often Korsakoff syndrome occurs without a background of Wernicke syndrome is disputed and bound up with the question of "alcoholic dementia" (see later in the text). Pathologic changes of Wernicke-Korsakoff are sometimes encountered unexpectedly at autopsy, suggesting the presence of subclinical or atypical forms, including unexplained coma.

The amnesia of Korsakoff syndrome is both anterograde, with inability to retain new information, and retrograde, with rather randomly lost recall for events months or years old. Alertness, attentiveness, and behavior are relatively preserved, but there tends to be a lack of spontaneous speech or activity. Confabulation is not invariable and, if initially present, tends gradually to disappear. Insight is usually impaired, and there may be flagrant anosognosia for the mental disturbance.

Pathobiology

The histopathologic lesions of Wernicke-Korsakoff syndrome consist of variable degrees of neuronal, axonal, and myelin loss; prominent blood vessels; reactive microglia, macrophages, and astrocytes; and, infrequently, small hemorrhages. Nerve cells may be relatively preserved in the presence of extensive myelin destruction and gliosis, and astrocytosis may predominate chronically.

Lesions affect the thalamus (especially the anterior and dorsomedial nuclei and the medial pulvinar), the hypothalamus (especially the mammillary bodies), the midbrain (especially the oculomotor and periaqueductal areas), and the pons and medulla (especially the abducens and medial vestibular nuclei). Such lesions sometimes produce abnormal signals on magnetic resonance imaging, including diffusion-weighted imaging. Diffusion tensor imaging reveals disruption of the fornix. In the anterior-superior vermis of the cerebellum, severe Purkinje cell loss and astrocytosis accompany lesser degrees of neuronal loss and gliosis in the molecular and granular layers.

Memory impairment in Korsakoff syndrome correlates best with lesions involving the anterior nuclei of the thalamus; other components of the so-called Papez circuit (eg, the mammillary bodies) probably contribute. The global confusion of Wernicke syndrome can occur without visible thalamic lesions and may be a biochemical disorder. Periaqueductal, oculomotor, or abducens nucleus lesions probably explain ophthalmoparesis. Both cerebellar and vestibular lesions likely contribute to ataxia.

Experimental and clinical evidence ascribes a specific role to thiamine in the Wernicke-Korsakoff syndrome. A genetic influence is implied because only a small minority of alcoholic or otherwise malnourished people are affected, and whites seem more susceptible than blacks.

Management and Outcome

Untreated Wernicke-Korsakoff syndrome can be fatal, and the mortality rate is 10% among treated patients. Concomitant liver failure, infection, or delirium tremens often makes the cause of death unclear. Postural hypotension and tachycardia call for strict bed rest; associated medical problems may require intensive care. The cornerstone of treatment is thiamine, 1,000 mg daily, until a normal diet can be taken; intramuscular or intravenous administration is preferred because thiamine absorption is impaired in chronic alcoholics. Hypomagnesemia may retard improvement after thiamine treatment; magnesium is therefore replaced, along with other vitamins. Protein intake may have to be titrated against the patient's liver status.

With thiamine treatment, the ocular abnormalities (especially abducens and gaze palsies) improve within a few hours and usually resolve within 1 week; in about 35% of patients, horizontal nystagmus persists indefinitely. Global confusion may improve in hours or days and usually resolves within 1 month, leaving Korsakoff amnesia in more than 80%. In less than 25% of these patients, there is eventual clearing of the memory deficit. Ataxia may improve in a few days, but recovery is complete in less than 50% of patients, and nearly 35% do not show improvement at all.

Nonalcoholics who develop Wernicke encephalopathy (eg, as a result of starvation or hyperemesis gravidarum) are less likely to have Korsakoff amnesia following treatment, consistent with a contributory role for alcohol itself in the pathogenesis of Wernicke-Korsakoff syndrome.

Alcoholic Cerebellar Degeneration

Cerebellar cortical degeneration may occur in nutritionally deficient alcoholics without Wernicke-Korsakoff syndrome (see Table 131.5). Instability of the trunk is the major symptom,

often with incoordination of leg movements. Arm ataxia is less prominent; nystagmus and dysarthria are rare. Symptoms evolve in weeks or months and eventually stabilize, sometimes even with continued drinking and poor nutrition. Ataxia without Wernicke disease is less likely to appear abruptly or to improve.

Pathologically, the superior vermis is invariably involved, with nerve cell loss and gliosis in the molecular, granular, and especially the Purkinje cell layers. There may be secondary degeneration of the olives and of the fastigial, emboliform, globose, and vestibular nuclei. Involvement of the cerebellar hemispheric cortex is exceptional and limited to the anterior lobes. Pathologic evidence of Wernicke disease may coexist, even though it is unsuspected clinically. Computed tomography and autopsies, moreover, have revealed cerebellar atrophy in alcoholics who were not clinically ataxic.

Although similar cerebellar lesions occur in malnourished nonalcoholics, most patients with alcoholic cerebellar degeneration do not have clinical or pathologic evidence of Wernicke disease. The disorder is probably the result of both nutritional deficiency and ethanol toxicity, perhaps involving glutamate.

Alcoholic Polyneuropathy

Alcoholic polyneuropathy is a sensorimotor disorder that stabilizes or improves with abstinence and an adequate diet (see **Table 131.5**). Neuropathy is found in most patients with Wernicke-Korsakoff syndrome but more often occurs alone. Paresthesia is usually the first symptom; there may be burning or lancinating pain and exquisite tenderness of the calves or soles. Impaired vibratory sense is usually the earliest sign; proprioception tends to be preserved until other sensory loss is substantial. Loss of ankle jerks is another early sign; eventually, there is diffuse areflexia. Weakness appears at any time and may be severe. Distal leg muscles are affected first, although proximal weakness may be marked. Radiologically demonstrable neuropathic arthropathy of the feet is common, as are skin changes (eg, thinning, glossiness, reddening, cyanosis, hyperhidrosis). Peripheral autonomic abnormalities are usually less prominent than in diabetic neuropathy but may cause urinary and fecal incontinence, hypotension, hypothermia, cardiac arrhythmia, dysphagia, dysphonia, impaired esophageal peristalsis, altered sweat patterns, or abnormal Valsalva ratio. Pupillary parasympathetic denervation is rare. The cerebrospinal fluid is usually normal except for occasional mild elevation of protein content.

Pathologically, the neuropathy is axonal, and clinical and experimental evidence suggests that it is both toxic and nutritional in origin. A clinical and pathologic study found that pure thiamine deficiency neuropathy differs from pure alcoholic neuropathy; alcoholic neuropathy is sensory dominant, slowly progressive, and painful and causes predominantly small-fiber axonal loss, whereas thiamine deficiency neuropathy is motor dominant and acutely progressive and causes predominantly large-fiber axonal loss.

Peripheral nerve pressure palsies, especially radial and peroneal, are common in alcoholics. Nutritional polyneuropathy may increase the vulnerability of peripheral nerves to compression injury in intoxicated individuals, who tend to sleep deeply in unusual locations and positions. Recovery usually takes days or weeks; splints during this period can prevent contractures.

Alcoholic Amblyopia

Alcoholic amblyopia is a visual impairment that progresses over days or weeks, with development of central or centrocecal scotomas and temporal disc pallor (see **Table 131.5**). Demyelination affects the optic nerves, chiasm, and tracts, with predilection for the maculopapular bundle. Retinal ganglion cell loss is secondary. Although amblyopia improves in patients who receive dietary supplements but continue to smoke and drink ethanol, direct toxicity from ethanol and from compounds in tobacco smoke (perhaps cyanide) could be contributory. Alcoholic amblyopia does not progress to total blindness; it may remain stable without change in drinking or eating habits. Improvement, which is often incomplete, nearly always follows abstinence and nutritional replacement.

Pellagra

Nicotinic acid deficiency in alcoholics causes pellagra, with dermatologic, gastrointestinal, and neurologic symptoms. Altered mentation progresses over hours, days, or weeks to amnesia, delusions, hallucinations, or delirium. Nicotinic acid therapy (plus other vitamins, deficiency of which can be contributory) usually results in prompt improvement.

Alcoholic Liver Disease

Alcoholic liver disease, progressing from reversible steatosis through steatohepatitis to cirrhosis, is a major cause of death among alcoholics. Altered mentation in an alcoholic always raises the possibility of hepatic encephalopathy, which may accompany intoxication, withdrawal, Wernicke syndrome, meningitis, subdural hematoma, hypoglycemia, or other alcohol states. Hepatic encephalopathy is discussed in detail in Chapter 124. Other neurologic disorders encountered in alcoholic cirrhotics include a poorly understood syndrome of altered mentation, myoclonus, and progressive myelopathy following portacaval shunting, as well as acquired chronic hepatocerebral degeneration, a characteristic syndrome of dementia, dysarthria, ataxia, intention tremor, choreoathetosis, muscular rigidity, and asterixis, which usually occurs in patients who have had repeated bouts of hepatic coma. Heavy ethanol use greatly increases the risk for acetaminophen hepatotoxicity and for cirrhosis and hepatocellular carcinoma in patients with hepatitis C infection.

Hypoglycemia

Metabolism of ethanol by alcohol dehydrogenase and of acetaldehyde by mitochondrial aldehyde dehydrogenase uses nicotinamide adenine dinucleotide (NAD). The resulting elevated NADH-to-NAD ratio impairs gluconeogenesis, and if food is not being eaten and liver glycogen is depleted, there may be severe hypoglycemia with altered behavior, seizures, coma, or focal neurologic deficit. Residual symptoms are common, including dementia. Even after appropriate treatment with intravenous 50% dextrose, these patients require close observation; blood glucose may fall again, with the return of symptoms and possibly permanent brain damage. Ethanol stimulates intestinal release of secretin, which aggravates reactive hypoglycemia, especially in children, by enhancing glucose-stimulated insulin release.

Alcoholic Ketoacidosis

In alcoholic ketoacidosis, β-hydroxybutyric acid and lactic acid accumulate in association with heavy drinking. The mechanism relates to starvation, increased lipolysis, and impaired fatty acid oxidation. Typical patients are young binge drinkers who stop drinking when they are overcome by anorexia. Vomiting, dehydration, confusion, obtundation, and hyperventilation ensue. Blood glucose may be normal, low, or moderately elevated, with little or no glycosuria. A large anion gap is accounted for by β-hydroxybutyrate, lactate, and lesser amounts of pyruvate and acetoacetate. Serum insulin levels are low, and serum levels of growth hormone, epinephrine, glucagon, and cortisol are high, but glucose intolerance usually clears without insulin and is not demonstrable on recovery. It is not unusual for patients to have repeated attacks of alcoholic ketoacidosis.

Alcoholics may have other reasons for metabolic acidosis with a large anion gap (eg, methanol or ethylene glycol poisoning). When β-hydroxybutyrate is the major ketone present, the nitroprusside test (Acetest) may be negative. Treatment includes infusion of glucose (and thiamine); correction of dehydration or hypotension; and replacement of electrolytes such as potassium, magnesium, and phosphate. Small amounts of bicarbonate may be given. Insulin is usually not needed.

Infection in Alcoholics

Alteration of white blood cell function contributes to the alcoholic's predisposition to infection (eg, bacterial and tuberculous meningitis). Infectious meningitis must always be considered in alcoholics with seizures or altered mental status, even when the clinical picture seems to be that of intoxication, withdrawal, thiamine deficiency, hepatic encephalopathy, hypoglycemia, or other alcoholic disturbances. Alcoholic intoxication is a risk factor for human immunodeficiency virus infection.

Trauma in Alcoholics

Thrombocytopenia, a direct effect of ethanol and a consequence of cirrhosis, increases the likelihood of intracranial hematomas after head injury. Abnormalities of clotting factors also increase the possibility of intracranial hematomas. Experimentally, moreover, acute ethanol enhances blood-brain barrier leakage around areas of cerebral trauma. Close observation is essential after even mild head injury in intoxicated patients; an abnormal sensorium must not be dismissed as drunkenness.

Alcohol and Cancer

Independently of tobacco, ethanol in moderate amounts increases the risk of carcinoma of the mouth, esophagus, pharynx, larynx, liver, and, probably, large bowel and breast.

Alcohol and Stroke

As with coronary artery disease, epidemiologic studies suggest that low to moderate amounts of ethanol decrease ischemic stroke risk, whereas higher amounts increase it. Meta-analysis of rigorously designed cohort and case-control studies found a J-shaped association between ethanol consumption and the risk of ischemic stroke and a linear association between ethanol consumption and the risk of hemorrhagic stroke. In the United States, the relationship holds for men and women; for blacks, whites, and Hispanics; and for spirits, beer, and wine. Whether extra risk is temporally associated with binge drinking and whether special benefit is conferred by wine (especially red wine) is less clear. In asymptomatic subjects, moderate ethanol consumption reduces the risk of both carotid atherosclerosis and leukoaraiosis. Ethanol could either prevent or cause stroke by several mechanisms. Acutely and chronically, ethanol causes hypertension. It reportedly lowers blood levels of low-density lipoproteins, raises levels of high-density lipoproteins, decreases fibrinolytic activity, increases or inhibits platelet reactivity, increases or decreases C-reactive protein, dilates or constricts cerebral vessels, and indirectly reduces cerebral blood flow through dehydration. The antioxidant properties of flavonoids in red wine might confer special protection. Alcoholic cardiomyopathy predisposes to embolic stroke.

Not all studies have found a protective effect of mild to moderate drinking on ischemic stroke, and some describe increased risk at any dose. Moreover, even if light drinking does reduce the risk of ischemic stroke (and coronary artery disease), the protection is offset by the enormous worldwide contribution of ethanol to all-cause mortality and morbidity. The Global Burden of Disease Study 2016 concluded that the only "level of consumption that minimizes health loss is zero."

Alcoholic Myopathy

Alcoholic myopathy is of two types. Chronic myopathy produces painless proximal weakness; serum creatine kinase can be elevated or normal, and, pathologically, there is atrophy affecting especially type 2 fibers (a nonspecific finding also seen with disuse or glucocorticoid toxicity). Cardiomyopathy may be present. Acute alcoholic myopathy consists of rhabdomyolysis, painful swelling, and myoglobinuria with renal injury. Both types of myopathy are attributed to direct effects of ethanol on muscle independent of malnutrition. Acute rhabdomyolysis often occurs hours or days after binge drinking. Workup includes checking for potassium or phosphate depletion, which are common in alcoholics. Treatment is supportive, and symptoms improve with abstinence.

Central Pontine Myelinolysis and Marchiafava-Bignami Disease

Central pontine myelinolysis occurs in both alcoholics and nondrinkers and is a consequence of overvigorous correction of hyponatremia. Marchiafava-Bignami disease is nearly always associated with alcoholism (including wine, beer, and whiskey). It is of unknown origin and causes symptoms, including death, that are scarcely explained by the characteristic callosal lesions. Central pontine myelinolysis is discussed in detail in Chapter 125.

Alcoholic Dementia

Whether ethanol, as a direct neurotoxin, can cause progressive mental decline in the absence of nutritional deficiency, brain trauma, or other indirect mechanisms has been controversial for decades. Properly controlled animal studies reveal dose-related impaired learning and neuropathologic changes in hippocampus and other brain regions. Brains of alcoholics without evident

nutritional deficiency have reduced volume especially affecting white matter; reports of cortical or hippocampal neuronal loss are less consistent, but neuropathologic changes appear to correlate with memory and other cognitive impairment. A plausible mechanism is inhibition of glutamate neurotransmission with receptor upregulation and rebound excitotoxicity. It is possible that ethanol neurotoxicity and thiamine deficiency are synergistic in this regard.

Numerous cohort and case-control studies addressing dose-related effects of ethanol on cognition have found that compared to nondrinking, low to moderate alcohol intake actually reduces the risk of dementia. As with ischemic stroke, in these studies, a J-shaped curve reflects ethanol's long-term effects on cognition: Compared to nondrinking, moderate intake reduces the risk of dementia and heavy intake increases it. Ethanol's protective effect is independent of its benefit on cerebrovascular disease. Wine, beer, and spirits are each protective, with some studies finding special benefit in red wine (perhaps related to antioxidant polyphenols such as resveratrol). A mechanism for ethanol's protection against nonvascular dementia is otherwise unclear.

Some studies have failed to find a protective effect of mild to moderate drinking on cognition, and some have described an increased risk at any dose compared to abstinence. The apparent risk reduction among light drinkers has been attributed to socioeconomic and educational status of light drinkers compared to never drinkers (and heavy drinkers).

Fetal Alcohol Spectrum Disorders

Ethanol ingestion during pregnancy causes congenital malformations and delayed psychomotor development. Major clinical features of the *fetal alcohol syndrome* (FAS) include cerebral dysfunction, growth deficiency, and distinctive facies (Table 131.6); less often, there are abnormalities of the heart, skeleton, urogenital organs, skin, and muscles. Neuropathologic abnormalities include absence or displacement of the corpus callosum, hydrocephalus, cerebellar dysplasia, abnormal neuronal migration, heterotopic cell clusters, and microcephaly. These changes occur independently of other potentially incriminating factors, such as maternal malnutrition, smoking, other drug use, or age. Binge drinking, which may produce high ethanol levels at a critical fetal period, may be more important than chronic ethanol exposure, and early gestation appears to be the most vulnerable period.

The face of a typical patient with FAS is distinctive and as easily recognized at birth as that of an infant with Down syndrome. Irritability and tremulousness with poor suck reflex and hyperacusis are usually present at birth and last weeks or months. Of these children, 85% perform more than two standard deviations below the mean on tests of mental performance; those who are not grossly retarded rarely have even average mental ability. Older children are often hyperactive and clumsy, and there may be hypotonia or hypertonia. Except for neonatal seizures, epilepsy is not a component of the syndrome.

Some children of alcoholic mothers have milder cognitive or behavioral features—for example, depression, anxiety, or hyperactivity. The broad continuum of ethanol's fetal effects is referred to as *fetal alcohol spectrum disorders* (FASDs), comprising mental, emotional, craniofacial, physiologic, and immunologic abnormalities that occur alone or in combination. Dysregulation of the hypothalamic-pituitary-adrenal axis, with hyperstress responses, is a major feature in many subjects.

TABLE 131.6 Clinical Features of Fetal Alcohol Syndrome

Majority	Minority
CNS	**Ears**
Mental retardation	Posteriorly rotated
Microcephaly	Poorly formed concha
Hypotonia	**Skeletal**
Poor coordination	Pectus excavatum or carinatum
Hyperactivity	Syndactyly, clinodactyly, or camptodactyly
Impaired growth	Limited joint movements
Pre- and postnatal for length and weight	Nail hypoplasia
Diminished adipose tissue	Radioulnar synostosis
Eyes	Bifid xiphoid
Short palpebral fissures	Scoliosis
Ptosis	Klippel-Feil anomaly
Strabismus	**Cardiac**
Epicanthal folds	Septal defects
Myopia	Great vessel anomalies
Microphthalmia	**Cutaneous**
Blepharophimosis	Abnormal palmar creases
Cataracts	Hemangiomas
Retinal pigmentary abnormalities	Infantile hirsutism
Nose	**Muscular**
Short, upturned	Diaphragmatic, inguinal, or umbilical hernias
Hypoplastic philtrum	Diastasis recti
Mouth	**Urogenital**
Thin vermilion lip borders	Labial hypoplasia
Retrognathia in infancy	Hypospadias
Micrognathia or prognathia in adolescence	Small rotated kidneys
Prominent lateral palatine ridges	Hydronephrosis
Cleft lip or palate	
Small teeth with faulty enamel	
Maxilla	
Hypoplastic	

Abbreviation: CNS, central nervous system.

Ethanol is directly teratogenic to many animals. Proposed mechanisms include apoptosis secondary to blockade of *N*-methyl-D-aspartate glutamate receptors during a critical period of synaptogenesis, toxicity to adhesion molecules essential for neuronal migration, and fetal vasospasm and central nervous system ischemia. Twin studies show genetic vulnerability to FASD (100% concordance in monozygotes, 63% in dizygotes), and ethanol has epigenetic effects which in animals are transgenerational. Epigenetics might explain observations that paternal drinking also carries risk for FASD.

In humans, the risk of alcohol-induced birth defects is established with more than 3 oz of absolute alcohol daily. Below that, the risk is uncertain; a threshold of safety has not been defined. As rates of ethanol use in the United States rose during the 1990s, so did the incidence of FAS. On the basis of data from the United States and France, it was estimated that the incidence of FASD is nearly 1% of all live births. The FASD may affect 1% of infants born to women who drink 1 oz of ethanol daily early in pregnancy. More than 30% of the offspring of heavy drinkers are affected by FAS, which thus may be the leading teratogenic cause of mental retardation in the Western world.

TREATMENT OF CHRONIC ALCOHOLISM

The literature on the treatment of alcoholism is voluminous, and strong opinions outweigh scientific data. Not all problem drinkers consume physically addicting quantities of ethanol, no personality type defines an alcoholic, and the relative roles of genetics and social deprivation vary from patient to patient. Of course, such variability of alcoholic populations means that no treatment modality (eg, psychotherapy, group psychotherapy, family or social network therapy, drug therapy, behavioral [aversion] therapy) or no single therapeutic setting (eg, general hospital, halfway house, vocational rehabilitation clinic, Alcoholics Anonymous) is appropriate for all. For example, the success rate of Alcoholics Anonymous has been estimated to be 34%.

Use of tranquilizing and sedating drugs is especially controversial because they may lead to switching of dependency or to drug-ethanol interactions. Some clinicians espouse short-term use of these drugs in doses high enough to reduce the psychological tensions that lead to ethanol use but low enough not to block symptoms of ethanol withdrawal.

Disulfiram inhibits aldehyde dehydrogenase and reduces the rate of oxidation of acetaldehyde, accumulation of which accounts for the symptoms that appear soon after someone taking disulfiram drinks ethanol. Within 5 to 10 minutes, there is throbbing headache, dyspnea, nausea, vomiting, sweating, chest pain, palpitations, hypotension, anxiety, and confusion. The severity and duration of these symptoms depend on the amount of ethanol drunk; severe reactions can last hours or be fatal and require hospital admission, with careful management of hypotension and cardiac arrhythmia.

Taken in the morning, when the urge to drink is least, disulfiram, 0.25 to 0.5 g daily, does not alter the taste for ethanol and helps only patients who strongly desire to abstain. Side effects of disulfiram that are unrelated to ethanol ingestion include drowsiness, psychiatric symptoms, and cardiovascular problems. Less common side effects include paranoia, impaired memory, ataxia, dysarthria, and even major motor seizures, which may be difficult to distinguish from ethanol effects. Hypersensitivity hepatitis and fulminant peripheral neuropathy can also occur.

Naltrexone and acamprosate are both U.S. Food and Drug Administration approved for treatment of alcoholism. Naltrexone might work by decreasing dopaminergic activity in reward circuits. Acamprosate might work by modulating glutamate neurotransmission and resetting a disrupted balance between GABA and glutamate systems. Placebo-controlled trials suggest that acamprosate (1,332-3,000 mg/d) is more effective than naltrexone in maintaining abstinence, whereas naltrexone (50-100 mg/d) is more effective in reducing heavy drinking and craving should drinking be resumed.

Topiramate affects both dopaminergic and glutamatergic pathways, and placebo-controlled trials demonstrate benefit (at doses ranging from 50 to 300 mg/d) both for maintaining abstinence and for reducing heavy drinking.

Drug Intoxication and Withdrawal 132

John C. M. Brust

KEY POINTS

1. Psychic dependence consists of craving and drug-seeking behavior; addiction is psychic dependence.
2. Physical dependence produces somatic withdrawal symptoms and signs.
3. A variety of agents produce psychic dependence, physical dependence, or both, and when more than one recreational drug is used, diverse symptoms of intoxication and withdrawal, as well as medical and neurologic complications, can be complicated and confusing.

INTRODUCTION

There are two kinds of drug dependence. *Psychic dependence* leads to craving and drug-seeking behavior. *Physical dependence* produces somatic withdrawal symptoms and signs. Depending on the particular drug and the circumstances of its administration, psychic and physical dependence can coexist or occur alone. *Addiction* is psychic dependence.

In the United States, dependence of one or both types is encountered with a variety of agents, licit and illicit (**Table 132.1**). Different classes of drugs produce diverse symptoms of intoxication and withdrawal as well as medical and neurologic complications.

In 2016, an epidemiologic survey of American adults reported a 9.9% lifetime prevalence of *Diagnostic and Statistical Manual of Mental Disorders* (5th edition) drug use disorder (not including tobacco or ethanol).

DRUGS OF DEPENDENCE

Opioids

Opioids include agonists, antagonists, and mixed agonist-antagonists (**Table 132.2**).

TABLE 132.1 Drugs of Dependence
Opioids
Psychostimulants
Sedatives/hypnotics
Marijuana
Hallucinogens
Inhalants
Phencyclidine
Anticholinergics
Ethanol
Tobacco

TABLE 132.2 Commonly Used Opioids
Agonist
• Camphorated tincture of opium (paregoric)
• Morphine
• Meperidine
• Methadone
• Fentanyl
• Hydromorphone
• Oxycodone
• Hydrocodone
• Propoxyphene
• Heroin
Antagonist
• Naloxone
• Naltrexone
Mixed Agonist-Antagonist
• Pentazocine
• Butorphanol
• Buprenorphine

Beginning in the 1990s, the United States and other countries experienced a steady rise in the use of prescription opioids to treat chronic noncancer pain. There soon emerged an epidemic of recreational use of these products, followed by an epidemic of illicit opioid use, including heroin, fentanyl, and "designer" fentanyl analogs and novel synthetic opioids. Of 72,306 drug overdose deaths reported in the United States during 2017, 84% were opioid-related.

Desomorphine, a reduction of codeine that is more potent but also often contains more impurities, is termed *crocodile* for the green-black skin lesions found on parenteral users.

Kratom, obtained from a Southeast Asian tree, contains mitragynine, which has opioid-like as well as serotonin-like effects. Kratom leaves can be chewed, ingested, or smoked.

At desired levels of intoxication, agonist opioids produce drowsy euphoria; analgesia; cough suppression; miosis; and often nausea, vomiting, sweating, pruritus, hypothermia, postural hypotension, constipation, and decreased libido. Taken parenterally or smoked (often in combination with alkaloidal crack cocaine), heroin produces a "rush," a brief ecstatic feeling followed by euphoria and either relaxed "nodding" or garrulous hyperactivity. Overdose causes coma, respiratory depression, and pinpoint (but reactive) pupils. For adults with respiratory depression, treatment consists of respiratory support and naloxone, 2 mg intravenously, repeated as needed up to 20 mg; for those with normal respirations, smaller doses (0.4-0.8 mg) are given to avoid precipitation of

withdrawal signs. Naloxone is short acting, and patients receiving it require close observation.

Fentanyl and fentanyl analogs, some of which are thousands of times more potent than morphine, require larger doses of naloxone to reverse respiratory depression. Escalating opioid overdose fatalities have led to nonprescription availability of naloxone as self-injection or nasal spray.

Opioid agonist withdrawal symptoms include irritability, lacrimation, rhinorrhea, sweating, yawning, mydriasis, myalgia, muscle spasms, piloerection, nausea, vomiting, abdominal cramps, fever, hot flashes, tachycardia, hypertension, and orgasm. In adults, seizures and delirium are not features of opioid withdrawal, which is rarely life threatening and can usually be prevented or treated with 20 mg of methadone taken once or twice daily. By contrast, untreated opioid withdrawal in newborns is severe and protracted, probably causes seizures, and is often fatal. Treatment is with titrated doses of methadone or paregoric; a barbiturate can be added if additional drug withdrawal is suspected or if seizures require treatment.

Effective pharmacotherapy for opioid dependence consists of substitution with oral methadone or buprenorphine. Treatment failure is usually attributable to inadequate dosage. Antagonist therapy with naltrexone proved disappointing.

Psychostimulants

Psychostimulants include amphetamine-like agents and cocaine (**Table 132.3**). 3,4-Methylenedioxymethamphetamine (MDMA; "ecstasy") appears to combine the psychostimulant properties of amphetamine with the hallucinogenic properties of lysergic acid diethylamide (LSD). An East African–Arabian shrub, khat (*Catha edulis*), is chewed for the effects of its psychoactive ingredient cathinone. Numerous "designer" analogs of cathinone, including methcathinone (ephedrone), mephedrone, and methylenedioxypyrovalerone (MDPV), are available on the Internet as "bath salts." Also available are "designer" psychostimulants chemically characterized as aminoindanes, piperazines, and pipradrol.

Desired effects of psychostimulants include alert euphoria with increased motor activity and physical endurance. Taken parenterally or smoked as alkaloidal cocaine ("crack") or methamphetamine ("ice"), psychostimulants produce a rush clearly distinguishable from that of opioids. With repeated use, there is stereotypic activity progressing to bruxism or other dyskinesias and paranoia progressing to frank hallucinatory psychosis. Overdose causes headache, chest pain, tachycardia, hypertension, flushing, sweating, fever, and excitement. There may be delirium, cardiac arrhythmia, myoclonus, seizures, myoglobinuria, shock, coma, and death. Malignant hyperthermia and disseminated intravascular coagulation are described. Treatment includes benzodiazepine sedation, oxygen, bicarbonate for acidosis, anticonvulsants, cooling, an antihypertensive (preferably an α-blocker such as phenoxybenzamine or a direct vasodilator such as sodium nitroprusside), respiratory and blood pressure support, and cardiac monitoring.

Psychostimulant withdrawal produces fatigue, depression, and increased hunger and sleep. Objective signs are few, but depression or somnolence can require treatment or even hospitalization.

An effective pharmacotherapy for psychostimulant dependence does not exist.

TABLE 132.3 Commonly Used Psychostimulants

Dextroamphetamine
Methamphetamine
Ephedrine
Pseudoephedrine
Methylphenidate
Pemoline
Phenmetrazine
Phentermine
Phenylpropanolamine (no longer produced in the United States)
3,4-Methylenedioxymethamphetamine (ecstasy)
Cocaine
Cathinone, methcathinone

Sedatives

Sedative agents include barbiturates, benzodiazepines, and miscellaneous products (**Table 132.4**). Benzodiazepines are often taken with recreational opioids, and a variety of "designer" benzodiazepines are currently available, often undetectable with standard assays. Desired effects and overdose with sedatives are similar to ethanol intoxication, although respiratory depression is much milder with benzodiazepines. Treatment is supportive; for severe benzodiazepine poisoning, there is a specific antagonist, flumazenil. Sedative withdrawal causes tremor and seizures, which can be prevented or treated with titrated doses of a barbiturate or a benzodiazepine such as lorazepam. Delirium tremens is a medical emergency requiring intensive care.

γ-Hydroxybutyric acid and two of its precursors, γ-butyrolactone and 1,4-butanediol, are notorious as "date rape" drugs. Often taken with ethanol, they cause sedation and respiratory depression. Treatment is supportive. Dependence occurs and withdrawal signs resemble those of other sedatives and ethanol, including seizures and delirium tremens.

Marijuana

Marijuana, from the hemp plant *Cannabis sativa*, contains many cannabinoid compounds, of which the principal psychoactive agent is Δ-9-tetrahydrocannabinol (THC). Hashish refers to preparations made from the plant resin, which contains high concentrations of psychoactive cannabinoids. Δ-9-THC acts at cannabinoid receptors in the brain, and the pharmaceutical development of synthetic receptor agonists was soon followed by their availability as recreational agents. Marketed as "Spice" or "K2," they are often many times more potent than Δ-9-THC.

Usually smoked, marijuana produces a relaxed dreamy euphoria, often with jocularity, disinhibition, depersonalization, subjective slowing of time, conjunctival injection, tachycardia, and postural hypotension. High doses cause auditory or visual hallucinations, confusion, and psychosis, but fatal overdose has not been documented. Withdrawal symptoms, other than craving, are minimal; there may be jitteriness, anorexia, and headache. Psychic dependence is common, however.

Synthetic cannabinoids ("K2," "Spice") frequently produce serious adverse effects, including psychosis, hallucinations, cardiac arrhythmia, myocardial infarction, vertigo, hypertension, protracted vomiting, seizures, acute kidney injury, stroke, and death. Withdrawal symptoms are more severe than with

TABLE 132.4 Sedative/Hypnotic Drugs
Barbiturates
• Phenobarbital
• Primidone
• Amobarbital
• Butalbital (only in mixtures, eg, Fioricet)
• Pentobarbital
• Secobarbital
• Methohexital
• Thiopental
Benzodiazepines
• Alprazolam
• Clorazepate
• Chlordiazepoxide
• Diazepam
• Lorazepam
• Oxazepam
• Flurazepam
• Temazepam
• Triazolam
• Clonazepam
• Midazolam
Miscellaneous Agents
• Buspirone
• Chloral hydrate
• Paraldehyde
• Diphenhydramine
• Ethchlorvynol
• Glutethimide
• Hydroxyzine
• Meprobamate
• Methaqualone (no longer produced in the United States)
• Zolpidem
• Zalepion
• γ-Hydroxybutyric acid

marijuana, and dependence liability is greater. Synthetic cannabinoids are not identified in toxicology screens, and there is no antidote for overdose.

A nonpsychoactive cannabinoid, cannabidiol (CBD), is FDA-approved for treating seizures in patients with Dravet or Lennox-Gastaut syndrome. Evidence supports the efficacy of oral cannabis extracts containing Δ-9-THC and CBD in treating spasticity, central pain, and urinary frequency in patients with multiple sclerosis. There is no evidence that smoked marijuana is of benefit in any neurologic disorder.

Hallucinogens

Hallucinogenic plants are used ritualistically or recreationally around the world. In the United States, the most popular agents are the indolealkylamines psilocybin and psilocin (from several mushroom species), the phenylalkylamine mescaline (from the peyote cactus), and the synthetic ergot compound LSD. Increasingly popular is the herb *Salvia divinorum*, which contains the kappa-opioid receptor agonist salvinorin A. Other synthetic hallucinogens carry such street names as "fly" and "dragonfly." "2-C" drugs are phenylalkylamines with hallucinogenic properties.

The acute effects of hallucinogens are perceptual (distortions or hallucinations, usually visual and elaborately formed), psychologic (depersonalization or altered mood), and somatic (dizziness, tremor, and paresthesia). Some users experience paranoia or panic and some, days to months after use, have flashbacks, the spontaneous recurrence of drug symptoms without taking the drug. High doses of LSD cause hypertension, obtundation, and seizures, but fatalities are usually the result of accidents or suicide. Treatment of overdose consists of a calm environment, reassurance, and, if necessary, a benzodiazepine. Withdrawal symptoms do not occur.

Inhalants

Recreational inhalant use is especially popular among children and adolescents, who sniff a wide variety of products, including aerosols, spot removers, glues, lighter fluid, fire-extinguishing agents, bottled fuel gas, marker pens, paints, and gasoline. Compounds include aliphatic hydrocarbons such as *n*-hexane, aromatic hydrocarbons such as toluene, and halogenated hydrocarbons such as trichloroethylene; in addition, nitrous oxide is sniffed from whipped-cream dispensers and butyl or amyl nitrite from room odorizers. Despite such chemical diversity, desired subjective effects are similar to those of ethanol intoxication. Overdose can cause hallucinations, seizures, and coma; death has resulted from cardiac arrhythmia, accidents, and aspiration of vomitus. Symptoms tend to clear within a few hours, and treatment consists of respiratory and cardiac monitoring. There is no predictable abstinence syndrome other than craving.

Phencyclidine

Developed as an anesthetic, phencyclidine (PCP or "angel dust") was withdrawn because it caused psychosis. As a recreational drug, it is usually smoked. The related agents ketamine, dextromethorphan, and methoxetamine are also used recreationally. Low doses of PCP cause euphoria or dysphoria and a feeling of numbness; with increasing intoxication, there is agitation, nystagmus, tachycardia, hypertension, fever, sweating, ataxia, paranoid or catatonic psychosis, hallucinations, myoclonus, rhabdomyolysis, seizures, coma, respiratory depression, and death. Treatment includes a calm environment with benzodiazepine sedation and restraints as needed, gastric suctioning, activated charcoal, forced diuresis, cooling, antihypertensives, anticonvulsants, and monitoring of cardiorespiratory and renal function. Neuroleptics, which can aggravate seizures, hypotension, and myoglobinuria, are best avoided. Symptoms can persist for hours or days. Psychic dependence to PCP occurs, but withdrawal signs are infrequent, usually consisting of nervousness, tremor, and upset stomach.

Anticholinergics

The recreational use of anticholinergics includes ingestion of the plant *Datura stramonium*, popular among American adolescents,

as well as use of antiparkinson drugs and the tricyclic antidepressant amitriptyline. Intoxication produces decreased sweating, fever, tachycardia, dry mouth, dilated unreactive pupils, and delirium with hallucinations. Severe poisoning causes myoclonus, seizures, coma, and death. Treatment includes intravenous (IV) physostigmine, 0.5 to 3 mg, repeated as needed every 30 minutes to 2 hours, plus gastric lavage, cooling, bladder catheterization, respiratory and cardiovascular monitoring, and, if necessary, anticonvulsants. Neuroleptics, which have anticholinergic activity, are contraindicated. There is no withdrawal syndrome.

COMPLICATIONS OF DRUG TOXIDROMES

Trauma

Trauma may be a consequence of a drug's acute effects, for example, automobile and other accidents during marijuana, inhalant, or anticholinergic intoxication; violence in psychostimulant or PCP users; and self-mutilation during hallucinogen psychosis. Trauma among users of illicit drugs, however, is most often the result of the illegal activities necessary to distribute and procure them. Overprescribing of sedatives is a major contributor to falls in the elderly.

Infection

Parenteral users of any drug are subject to an array of local and systemic infections, which in turn can affect the nervous system. Hepatitis leads to encephalopathy or hemorrhagic stroke. Cellulitis and pyogenic myositis produce more distant infection, including vertebral osteomyelitis with myelopathy or radiculopathy. Endocarditis, bacterial or fungal, leads to meningitis, cerebral infarction or abscess, and septic ("mycotic") aneurysm. Tetanus, often severe, affects drug injectors, and botulism occurs either at injection sites or, among cocaine snorters, in the nasal sinuses. Malaria affects heroin users in endemic areas. Anthrax has affected users of contaminated heroin.

Parenteral drug use is a major risk factor for human immunodeficiency virus (HIV) infection. Users are subject to the same neurologic complications that affect nondrug users, especially syphilis and tuberculosis, including drug-resistant forms. Because of promiscuity and associated sexually transmitted diseases, nonparenteral cocaine users are also at increased risk for AIDS. Heroin and cocaine are themselves immunosuppressants (heroin users were vulnerable to unusual fungal infections before the AIDS epidemic); yet, their use in HIV-seropositive individuals does not seem to accelerate the development of AIDS.

Progressive myelopathy occurs in parenteral drug users infected with either human T-lymphotropic virus (HTLV)-I or HTLV-II.

Seizures

Seizures are a feature of withdrawal from sedatives, including, infrequently, benzodiazepines. Methaqualone (no longer legally available in the United States) and glutethimide have reportedly caused seizures during intoxication. Opioids lower seizure threshold, but seizures are seldom encountered during heroin overdose. Myoclonus and seizures more often occur in meperidine users, a consequence of the active metabolite normeperidine. Seizures may occur in cocaine users without other evidence of overdose. In animals, repeated cocaine administration produces seizures in a pattern suggestive of kindling. Amphetamine and other psychostimulants are less epileptogenic than cocaine, but seizures did affect users of the no longer legal over-the-counter anorectic phenylpropanolamine. A case-control study found that marijuana was protective against the development of new-onset seizures.

Stroke

Illicit drug users frequently abuse ethanol and tobacco, increasing their risk for ischemic and hemorrhagic stroke. Parenteral drug users are subject to stroke through systemic complications such as hepatitis, endocarditis, and AIDS. Heroin users develop nephropathy with secondary hypertension, uremia, and bleeding. Heroin has also caused stroke in the absence of other evident risk factors, perhaps through immunologic mechanisms.

Amphetamine users are prone to intracerebral hemorrhage following acute hypertension and fever. They are also at risk for occlusive stroke secondary to cerebral vasculitis affecting either medium-sized arteries (resembling polyarteritis nodosa) or smaller arteries and veins (resembling hypersensitivity angiitis). Ischemic and hemorrhagic stroke is also a frequent consequence of cocaine use, regardless of route of administration. Most hemorrhagic strokes are probably consequent to acute surges of hypertension; most ischemic strokes are probably secondary to cocaine's vasoconstrictive actions on cervical and intracranial circulation. Cerebral saccular aneurysms and vascular malformations are often found in patients undergoing angiography for cocaine-related intracranial hemorrhage.

Because of their association with stroke, diet pills and decongestants containing phenylpropanolamine were banned by the U.S. Food and Drug Administration. Similar association led to a number of states banning dietary supplements containing ephedra. Intracerebral and subarachnoid hemorrhages are described in MDMA users.

Anecdotal and epidemiologic reports describe marijuana use as a risk factor for ischemic stroke. A population survey found that subjects who used marijuana at least weekly had 4.7 times the risk of stroke compared to nonusers. A proposed mechanism is reversible cerebral vasoconstriction. Stroke is also described in synthetic cannabinoid users.

LSD and PCP are vasoconstrictive, and occlusive and hemorrhagic strokes have followed their use.

Altered Mentation

Dementia in illicit drug users may be the result of concomitant ethanol abuse, malnutrition, head trauma, or infection. Parenteral drug users are at risk for HIV encephalopathy. Whether the drugs themselves cause lasting cognitive or behavioral change is more difficult to establish, for predrug mental status is nearly always uncertain and many drug users are probably self-medicating preexisting psychiatric conditions (eg, cocaine for depression).

Clinical studies describe significant impairments in working memory, verbal fluency, and "cognitive impulsivity" among users of opioids, including prescription opioids and methadone maintenance therapy. Functional imaging studies demonstrate reduced cerebral gray matter density, decreased white matter fractional anisotropy, and abnormal connectivity patterns.

Controversy exists over whether psychostimulants predispose to lasting depression or if PCP predisposes to schizophrenia.

In animals and humans, methamphetamine damages both dopaminergic and serotonergic nerve terminals, and MDMA destroys serotonin nerve terminals. Impaired memory is described in abstinent methamphetamine users, and among MDMA users followed prospectively, only a few years of use was associated with cognitive decline and abnormal fractional anisotropy in multiple brain areas.

Cocaine is not neurotoxic to axon terminals, and reports on the long-term cognitive effects of cocaine are conflicting. Studies of animals exposed to cocaine demonstrate structural brain abnormalities.

Clinical, imaging, and animal studies convincingly demonstrate that marijuana use, especially during adolescence, causes lasting behavioral and cognitive alteration. Long-term marijuana users demonstrate axonal microstructural alterations and volume reductions in brain regions rich in cannabinoid receptors. Epidemiologic studies provide persuasive evidence that marijuana is a significant risk factor for schizophrenia.

Sedatives can cause reversible dementia in the elderly and delayed learning in small children.

Lead encephalopathy is described in gasoline sniffers, and cerebral white matter lesions with dementia are described in toluene sniffers.

Fetal Effects

The effects of illicit drugs on intrauterine development are also difficult to separate from damage secondary to ethanol, tobacco, malnutrition, and inadequate prenatal care or home environment. Infants exposed in utero to heroin have reportedly been small for gestational age, at risk for respiratory distress, and cognitively impaired later in life.

Prenatal methamphetamine exposure is an independent risk factor for fetal growth restriction. A 10-year prospective study controlling for such confounders as additional drugs and environmental influences concluded that first-trimester cocaine exposure confers risk for reduced height, weight, and head circumference and for abnormal behavior. Reviews of studies addressing maternal cocaine use during pregnancy found convincing association with microcephaly, perinatal cerebral infarction, brain abnormalities on magnetic resonance diffusion tensor imaging, and reduced volumes of cortical gray matter. Animal studies demonstrate that in utero, cocaine exposure detrimentally affects learning.

Long-term cohort studies of in utero marijuana exposure have demonstrated impaired attention and memory and smaller head size. Animal studies show abnormal axonal connectivity.

Organic solvents are teratogenic in animals.

Miscellaneous Effects

Guillain-Barré–type neuropathy and *brachial* or *lumbosacral plexopathy*, probably immunologic in origin, have been associated with heroin use. (Brachial plexopathy has also resulted from septic aneurysm of the subclavian artery.) Severe sensorimotor polyneuropathy occurs in sniffers of glue containing *n*-hexane. *Myoglobinuria* and renal failure have followed use of heroin, amphetamine, cocaine, and PCP.

Myeloneuropathy, indistinguishable from cobalamin deficiency, occurs in nitrous oxide sniffers. Anemia is absent, and serum vitamin B_{12} levels are usually normal. The mechanism is inactivation of the cobalamin-dependent enzyme methionine synthetase.

Possibly vascular in origin, acute myelopathy occurs in parenteral heroin users.

Severe irreversible parkinsonism developed in Californians exposed to a meperidine analog contaminated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, a metabolite of which is toxic to neurons in the substantia nigra. Symptoms responded to levodopa.

Dementia, *ataxia*, *quadriparesis*, *blindness*, and *death* occur in smokers of heroin pyrolysate ("chasing the dragon"). Autopsies show spongiform changes in the central nervous system white matter. The responsible toxin has not been identified.

Parenteral methcathinone users are subject to *extrapyramidal gait disturbance* and *hypophonia*, a consequence of hypermagnesemia following the use of potassium permanganate in the preparation of the drug.

Blindness developed in a heroin user whose mixture contained large quantities of quinine.

Chronic cocaine users experience *dystonia* and *chorea*, and cocaine can precipitate symptoms in patients with *Tourette syndrome*.

Marijuana inhibits luteinizing and follicle-stimulating hormones, causing *reversible impotence* and *sterility* in men and *menstrual irregularity* in women.

Ataxia and *cerebellar white matter* changes have occurred in toluene sniffers.

Hallucinogen users not only experience flashbacks but, in some cases, visual phenomena persist for years (*hallucinogen-persisting perception disorder*).

Cocaine is frequently adulterated with the immunomodulatory drug levamisole, complications of which include leukopenia, vasculitis, and leukoencephalopathy.

A common adulterant in the preparation of synthetic cannabinoids is the vitamin K anticoagulant brodifacoum. Intracranial hemorrhage is described in users.

Neurotoxicology 133

Christopher Zammit and Stephan A. Mayer

KEY POINTS

1. Xenobiotics are substances within an organism that are not usually found in or produced by that organism.
2. Anticholinergic intoxication produces flushed skin, anhidrosis, delirium, and urinary retention, among other symptoms.
3. Serotonin syndrome causes tremor, ocular and extremity clonus, hyperreflexia, agitation, or diaphoresis after a serotoninergic agent is introduced.
4. Neuroleptic malignant syndrome causes mental status changes, muscular rigidity, hyperthermia, and autonomic disturbances.
5. Benzodiazepines are the preferred treatment for toxin-induced seizures.

INTRODUCTION

Xenobiotics are substances within an organism that are not normally found in or produced by that organism. *Neurotoxicology* refers to the adverse effects of xenobiotics, or poisons, on the nervous system. This is a massive field with well over 350 documented neurotoxic xenobiotics. To facilitate digestibility and clinical use of the topic, this chapter focuses on acute neurotoxicology. Chronic neurotoxic associations and syndromes are listed and briefly described. Neurotoxicology with reference to neurodevelopment, withdrawal syndromes, and psychiatric disorders, such as psychosis and mood disorders, are minimally discussed.

Xenobiotics can include medications; industrial chemicals such as heavy metals, air pollution, solvents, and vapors; substances produced by other organisms (eg, marine toxins, snake venom); food additives; herbal products and botanicals; recreational drugs; and insecticides, herbicides, rodenticides, and other household products. Acute neurotoxic events have been better described and causational links are more convincing. Neurotoxic effects from chronic exposures are more challenging to prove because the clinical symptoms may be temporally distant from the exposure or the concentration of the xenobiotic in the organism is so low that it may be difficult to detect.

EPIDEMIOLOGY

The specific incidence, prevalence, and demographics of specific neurotoxins, where available, are mentioned individually in the following sections. Age, gender, and certain comorbidities have been associated with the occurrence and severity of various toxicity syndromes.

Clinical toxicity is more commonly seen in older patients for several reasons. Age-related decrements in renal and hepatic function impair the ability to clear and eliminate xenobiotics. Reductions in neuronal quantity increase the sensitivity to the presence of xenobiotics. Finally, changes in mitochondrial function are known to occur with advanced age, increasing the possibility of excitotoxicity.

Gender has been associated with certain clinical manifestations in the setting of xenobiotics. Bruxism and dystonia are more prevalent in males, whereas tardive dyskinesia and parkinsonism are more frequently observed in females.

Comorbidities can increase the risk of neurotoxicity if they impair elimination of the xenobiotic (eg, renal insufficiency or cirrhosis) or facilitate its entry into the central nervous system (CNS) via disturbance of the blood-brain barrier (eg, meningitis, encephalitis). The presence of or prior exposure to other nonneurotoxic xenobiotics (eg, prescription medications) can influence the relative neurotoxicity of a xenobiotic by impairing its metabolism or elimination; hastening its conversion to a neurotoxic metabolite; and altering gene expression, neurotransmitter production, release, breakdown, and neurotransmitter receptor density or function. Efflux transporters on the blood-brain barrier, such as P-glycoproteins and organic acid transport proteins, are typically responsible for shuttling xenobiotics out of the CNS. Some medications and conditions are known to inhibit the function of P-glycoproteins (Table 133.1), increasing the concentration of the neurotoxic xenobiotics in the CNS. Some nutrition inadequacies, such as heavy metal deficiencies, can enhance the uptake of neurotoxic xenobiotics. Lastly, some neurologic disorders can be unmasked with the introduction of a xenobiotic (Table 133.2).

TABLE 133.1 Selected P-glycoprotein Inhibitors and Inducers

Inhibitors	Inducers
• Amiodarone	• Avasimibe
• Ceftriaxone	• Carbamazepine
• Clarithromycin, erythromycin	• Clotrimazole
• Cyclosporine	• Phenytoin
• Diltiazem	• Phenobarbital
• Hydrocortisone	• Rifampin
• Ketoconazole, itraconazole	• St. John's wort
• Nicardipine	• Tipranavir/ritonavir
• Propranolol	• Prazosin
• Ritonavir, saquinavir, nelfinavir	• Progesterone
• Tamoxifen	
• Tacrolimus	
• Verapamil	

TABLE 133.2 Neurologic Disorders Unmasked by Xenobiotics

Xenobiotic	Neurologic Disorder
Aminoglycosides	Myasthenia gravis
Vincristine	Charcot-Marie-Tooth
Antiretrovirals	Human immunodeficiency virus–related peripheral neuropathy

PATHOBIOLOGY

For neurotoxicity to occur, a xenobiotic must come into contact with the nervous system. CNS toxicity occurs when certain xenobiotics cross the blood-brain barrier via endocytosis, transport proteins, or diffusion. Lipophilic xenobiotics gain entry via diffusion, whereas hydrophilic ones must engage with one of the two other mechanisms.

Neurotoxicity occurs through a variety of mechanisms that are summarized in Table 133.3. The most elusive mechanism to associate with a xenobiotic are those that alter gene expression because the appearance of clinical toxicity may not occur until the xenobiotic has been eliminated from the system. *Excitotoxicity* is a common end point for several of the neurotoxic xenobiotics whether it is through activation of excitatory pathways or via retarded energy production, which leads to metabolic failure in the setting of neuroexcitation.

Neurotoxicity can manifest pathophysiologically as central or peripheral demyelination, neuronal death, clinical syndromes related to the activation or inhibition of neurotransmitter pathways, or impaired function due to disrupted neuronal or glial processes.

CLINICAL FEATURES

Neurotoxic presentations are protean and may include seizures or status epilepticus, ataxia, tremor, encephalopathy, movement disorders, peripheral neuropathies, lethargy, stupor, coma, cognitive impairment, neuropsychiatric behavioral disturbances, or diffuse weakness. Lateralization of neurologic deficits is uncommon unless the toxicity is unmasking a prior neurologic insult.

Seizures are a not uncommon neurotoxic presentation. Table 133.4 lists some xenobiotics known to cause seizures. A variety of movement disorders have been reported to be caused by xenobiotics, including dyskinesias, akathisia, chorea, parkinsonism, dystonias, myoclonus, and asterixis (Table 133.5). Tremors associated with xenobiotics, which can be resting, sustention, or kinetic, are summarized in Table 133.6. Medications and toxins known to cause ataxia are listed in Table 133.7. Cranial and/or peripheral neuropathies can be the result of demyelination, axonal injury, or failed transmission at the neuromuscular junction (NMJ) or of the action potential and present with diffuse weakness, autonomic dysfunction, and/or sensory disturbances. Tables 133.8 and 133.9 summarize xenobiotics associated with each of these mechanisms. Lastly, Table 133.10 lists xenobiotics associated with myopathies, which present with diffuse myalgias and weakness.

TABLE 133.3 Mechanisms of Neurotoxicity

Cellular	Membrane	Cellular Signaling
• Oxidative injury/ neuroexcitation	• Disrupted ion homeostasis	• Altered neurotransmitter production, release, metabolism, or uptake
• Disturbed energy production	• Antagonism/ agonism of ion channels	• Blunted or exaggerated neurotransmitter receptor activation
• Altered gene expression or transcription		• Mimics neurotransmitter, stimulating receptor
• Altered protein function or structure		

DIAGNOSIS

Many of the neurotoxic xenobiotics or their metabolites can be detected in the serum, urine, or other body tissues or fluids. Of note, the detection of a neurotoxic xenobiotic should not universally lead the clinician to conclude that it is the culprit for the clinical complaint or ailment. The clinical symptoms should be consistent with a well-documented neurotoxicity or syndrome in a patient with a known exposure to the toxin. Otherwise, a neurotoxin can be suspected to be the cause of the clinical symptoms, but other etiologies should be excluded. Improving symptoms in the setting of neurotoxin elimination serves to increase confidence in the diagnosis of neurotoxicity. Additional diagnostic clues can be obtained when certain odors are perceived that are suggestive of a particular xenobiotic (Table 133.11).

TREATMENT

In any acute neurotoxic presentation, the first steps are to rule out hypoglycemia and remove the victim from the exposure. If the toxin is on the patient's clothing or skin, they should be promptly decontaminated. Health care workers should employ universal precautions when approaching such patients to prevent self-exposure. Entry into an enclosed environment should be delayed until decontamination can be performed to not poison other patients or health care providers. If providing glucose, *thiamine* 100 mg intravenous (IV) should be considered prior to doing so as to not induce Korsakoff syndrome in those with a (relative) thiamine deficiency. In hypopneic or apneic patients with miotic pupils, *naloxone* 0.4 to 2.0 mg IV can be administered to reverse a potential opiate overdose.

The core components of treating any neurotoxic presentation include reducing absorption of the toxin, enhancing its elimination, provision of an antidote, and supportive care. Performing gastric lavage, administering activated charcoal, and/or providing whole bowel irrigation has the potential to reduce the absorption of an ingested xenobiotic.

Gastric lavage has largely become antiquated because it is resource intensive, often requires endotracheal intubation, and has not been objectively shown to be beneficial. However, it still has a role in the hyperacute ingestions (within 1 h) of highly toxic substances that are not effectively absorbed by activated charcoal and do not have an effective antidote. Due to the risk for inadvertent aspiration, hydrocarbons and alkaline caustics should not be lavaged.

TABLE 133.4 Xenobiotics Known to Induce Seizures[a]

Xenobiotic Category	Specific Agents
Antihistamines	**Diphenhydramine**, doxylamine
Anticholinergics	Benztropine mesylate, scopolamine
Antibiotics	**Isoniazid**, β-lactams (penicillins, cephalosporins, carbapenems), ciprofloxacin
Antivirals	Acyclovir, valacyclovir, amantadine
Antimalarials	**Chloroquine**, mefloquine, pyrimethamine
Nonsteroidal anti-inflammatories	Mefenamic acid, phenylbutazone (veterinary NSAID), ibuprofen, naproxen, salicylates
Opioids	*Meperidine*, propoxyphene, tramadol
Local anesthetics	Bupivacaine, lidocaine, procaine, tetracaine
Antiepileptics	Phenytoin, carbamazepine, valproic acid, ethosuximide
Antineoplastics	Bleomycin, busulphan, carmustine, chlorambucil, cisplatin, cytarabine, mechlorethamine, methotrexate, vinblastine, vincristine
Antidepressants	***Bupropion***, fluoxetine, maprotiline, mianserin, trazodone
Tricyclic antidepressants	All of them
Antipsychotics, mood stabilizers	All antipsychotics, especially *chlorpromazine*, *clozapine*, and *phenothiazines*, lithium
Stimulants	Methylphenidates, pemoline
Antiemetics	*Prochlorperazine*, metoclopramide, *promethazine*, droperidol
Cardiovascular drugs	Propranolol, flecainide, digoxin
Ergotamines	Dihydroergotamine, ergotamine
Methylxanthines	Caffeine, **theophylline**
Other medications	Levodopa, baclofen, levothyroxine, allopurinol, bromocriptine, colchicine, corticosteroids
Alcohols	Ethylene glycol, methanol
Recreational drugs	Cocaine, MDMA (ecstasy or molly), amphetamines, phencyclidine, nicotine
Rodenticides	**TETS**, thallium, zinc phosphide, arsenic
Pesticides/insecticides	Pyrethrins (insecticides), organochlorines (eg, lindane), organic phosphorus compounds (eg, malathion)
Botanicals	**Cicutoxin** (water hemlock), picrotoxin (*Anamirta cocculus*, plant and performance enhancers), ackee fruit, daphne, rhododendrons
Heavy metals	Thallium, arsenic, copper, lead, nickel, manganese
Household and industrial toxins	Carbon monoxide, **camphor**, cyanide, fluoride, phenols (eg, paint strippers), 1,4-dichlorobenzene (eg, mothballs), **monomethylhydrazine (rocket fuel)**, carbon disulfide, hydrogen sulfide, methyl bromide, triazine, various hydrocarbons, chlorophenoxy herbicides
Ingestion	Domoic acid (amnestic shellfish poisoning), **ciguatera** (moray eels, barracuda, red snapper), tetrodotoxin (puffer fish species, blue-ringed octopus, horseshoe crab), **gyromitrin (*Gyromitra* fungus species)**, herbals (lobelia, passion flower, periwinkle, wormwood, *Galega*, mandrake, jimson weed)
Envenomations	Pit viper, tick bite, scorpion

Abbreviations: MDMA, 3,4-methylenedioxymethamphetamine; NSAID, nonsteroidal anti-inflammatory drug; TETS, tetramethylenedisulfotetramine.
[a]The **xenobiotics** in **bold** are reported to have caused status epilepticus, and those in *italics* frequently cause seizures. **Strychnine poisoning** causes nonepileptic convulsions and is intentionally excluded from these lists.

TABLE 133.5 Movement Disorders Associated With Xenobiotics

Chorea	Myoclonus	Reversible Parkinsonism	Irreversible Parkinsonism
• Anticholinergics	• Anticholinergics	• Carbon disulfide	• Calcium channel blockers
• Antiepileptics	• Antiepileptics	• Carbon monoxide	• Chemotherapeutics (several)
• Levodopa	• Sedatives/hypnotics	• Copper	• Cyclosporine
• Amantadine	• Bismuth	• Cyanide	• Antipsychotics
• Bromocriptine	• Ethanol	• Heroin	• Antiemetics
• Carbon monoxide	• Lead	• Manganese	• Sertraline
• Corticosteroids	• Levodopa	• MPTP	• Valproate
• Dopamine antagonists	• Mercury		• Trazodone
• Toluene	• Tricyclic antidepressants		• Progesterone
• Sympathomimetics			• Kava-kava
• Oral contraceptives			
• Lithium			
Dyskinesia	**Akathisia**	**Dystonia**	
• Antidopaminergics	• Antidepressants	• Anticholinergics	
• Calcium channel blockers	• Antidopaminergics	• Dopamine antagonists	
	• Calcium channel blockers	• Levodopa	
	• Tetrabenazine		
	• AMPT		

Abbreviations: AMPT, α-methyl-p-tyrosine; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

TABLE 133.6 Xenobiotics Associated With Tremors

Resting Tremor	Sustention Tremor	Kinetic Tremor
• Hypoglycemics	• Amiodarone	• Amiodarone
• Calcium channel blockers	• Hypoglycemics	• Hypoglycemics
• Antidopaminergics	• Methylxanthines	• Sedative/hypnotics
• Carbon disulfide	• Carbon disulfide	• Carbamazepine
• Carbon monoxide	• Carbon monoxide	• Colistin
• Captopril	• Antidopaminergics	• Lithium
• Lithium	• Sympathomimetics	• Phenytoin
• Manganese	• MAOIs	• Valproic acid
• Methanol	• TCAs	
• MPTP	• Ethanol	
• Phenytoin	• Sedative/hypnotics	
• Tetrabenazine	• Phenytoin	
	• Valproic acid	
	• Phencyclidine	
	• Corticosteroids	
	• Arsenic, lead	
	• Lithium	
	• Levodopa	

Abbreviations: MAOIs, monoamine oxidase inhibitors; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; TCAs, tricyclic antidepressants.

Similarly, the use of activated charcoal has decreased over the years because published evidence has failed to demonstrate appreciable efficacy. It is not to be used in those with a depressed level of consciousness, at risk for aspiration, and after some ingestions (Table 133.12). Whole bowel irrigation can be considered in those with an ingestion of a highly toxic sustained-release medication or xenobiotics that are not absorbed by activated charcoal.

Options for enhanced elimination include the provision of hemodialysis, hemoperfusion, urinary alkalinization, and rarely, exchange transfusion. The elimination of protein-bound xenobiotics is not appreciably enhanced with dialysis.

TABLE 133.7 Medications and Toxins Associated With Ataxia

- **Antiepileptics:** phenytoin, carbamazepine, oxcarbazepine, gabapentin, levetiracetam, lamotrigine, valproate sodium
- **Antineoplastic agents:** cytarabine, methotrexate, 5-fluorouracil, asparaginase
- **Heavy metals:** methylmercury, arsenic, lead, thallium, manganese
- **Lithium**
- **Hydrocarbons:** toluene, benzene, *n*-hexane, carbon tetrachloride
- **Sedatives/hypnotics:** benzodiazepines, barbiturates, ethanol
- **Amiodarone**
- **Carbon disulfide**
- **Cyclosporine**
- **Tacrolimus**
- **Metronidazole**
- **Bismuth**
- **High-dose corticosteroids**

Table 133.13 summarizes some neurotoxins and their antidotes. Benzodiazepines are the preferred treatment for neurotoxin-induced seizures. Ion channel dysfunction is a not uncommon mechanism for several of the seizure-inducing neurotoxins, which may be made worse with the administration of many of the commonly used antiepileptics (eg, phenytoin or valproic acid).

OUTCOME

Outcomes following a neurotoxin exposure are dependent on the pathophysiology of the neurotoxic insult. Mechanisms that lead to neuronal injury or death are more likely to produce permanent deficits than mechanisms that interfere with the functioning of neurotransmitters or cell signaling. In some circumstances, toxins that alter cell signaling or action potential propagation can lead to permanent changes in the structure, function, or density of neurotransmitter receptors or ion channels, increasing the possibility of lasting effects. Many of the toxicities are dependent on the peak concentration of the toxin in the patient and its concentration over time. Clinical outcomes can be worsened with delays in toxic elimination or the provision of an antidote. Reexposure tends to produce exponentially severe clinical symptoms, which are more likely to be permanent.

COMMON NEUROTOXIDROMES

Neurotoxins with similar mechanisms of action typically produce distinct syndromes that allow for their clinical recognition and commonalities in their treatment. This section summarizes several syndromes, provides lists of known culprit neurotoxins, outlines treatment options, and describes their expected clinical outcomes.

Anticholinergic Toxicity

Approximately 20,000 patients are exposed to anticholinergic xenobiotics per year. This is likely an underestimate because this only accounts for the recognized and reported cases. To be specific, these substances have antimuscarinic properties that produce their characteristic clinical symptoms. Xenobiotics with antinicotinic actions are separate and distinct from those mentioned here. Hundreds of medications have anticholinergic properties, which places many patients at risk for subtle toxicities that may manifest in mild behavioral or cognitive disturbances.

Clinical Features

Clinical symptoms of anticholinergic toxicity are summarized in Table 133.14 and are secondary to antimuscarinic actions. Patients rarely have all of the associated symptoms; tachycardia and dry mucous membranes are the most commonly seen. The most severe exposures produce hyperthermia, coma, and/or seizures. Xenobiotics with antimuscarinic activity are summarized in Table 133.15. Note that ophthalmic drops are absorbed systemically and therefore can produce anticholinergic symptoms in the setting of liberal administration. Additionally, recreational drugs have been contaminated with anticholinergic adulterants on more than one occasion (eg, heroin tainted with scopolamine).

Treatment

Treatment is largely supportive. Hyperthermia should be rapidly corrected with conductive and evaporative measures. Agitation and

seizures should be controlled with benzodiazepines such as *lorazepam* 2 to 4 mg IV repeated as needed. Antipsychotics should be avoided because they lower the seizure threshold and nearly all of them have antimuscarinic actions as well (see Table 133.15). Antiepileptics are typically not effective in the treatment of anticholinergic-induced seizures and their action on ion channels may increase the risk for cardiac arrhythmias. Status epilepticus is rarely the result of antimuscarinic toxicity; if present, other etiologies should be considered.

Physostigmine is an acetylcholinesterase (AChE) inhibitor that has been used to treat anticholinergic toxicity and is the only AChE inhibitor that crosses the blood-brain barrier. A dose of 0.02 mg/kg can be given over 5 minutes and repeated every 10 to 15 minutes. It has a rapid onset and short duration of action (~1 h). Extreme caution must be exercised when using physostigmine because it may produce symptoms of cholinergic toxicity, severe bradycardia, and even asystole. Anticholinergic toxicity is quite rarely fatal with supportive therapy; therefore, the use of physostigmine is rarely justified, given its associated risks. It is contraindicated in atrioventricular and intraventricular conduction delays and in tricyclic antidepressant toxicity.

Sympathomimetic Toxicity and Acute Excited State

The clinical presentation of patients with a toxin-induced excited delirium and those with sympathomimetic toxicity is largely indistinguishable. The risk factors, patient characteristics, and management are largely the same as well, so they are discussed together. Some pertinent idiosyncrasies of some of the xenobiotics are mentioned. Table 133.16 summarizes the various agents known to cause excited delirium.

Widespread use of prescription, botanical, and recreational stimulants and hallucinogens has brought the neurotoxic effects of these substances into daily clinical conversation. There are well over 100,000 presentations to emergency departments each year in the United States related to these xenobiotics. Their neurotoxic effects are exerted through manipulation of the mechanisms carried out by the central monoamine neurotransmitters (serotonin, norepinephrine, and dopamine). This includes increased neurotransmitter release, exaggerated effects at its postsynaptic receptor, decreased neurotransmitter breakdown, and receptor agonism or antagonism, among other mechanisms. In several cases, the culprit xenobiotic's effects are not isolated to one neurotransmitter or receptor, making their clinical manifestations less predictable and reliable.

Clinical Features

Clinically, these patients will present with hypervigilance, agitation, paranoia, hallucinations, stereotyping, dyskinesias, choreoathetoid movements, tachycardia, hypertension, mydriasis, and/or diaphoresis. More severe toxicity can cause delirium, combativeness, severe hyperthermia (>40°C), and seizures. Wide complex tachycardia can be seen in the setting of cocaine- (due to its sodium channel blockade) or rhabdomyolysis-induced hyperkalemia. The patient may have a depressed level of consciousness

due to other coingested intoxicants. Diaphoresis is absent in anticholinergic toxicity, making this finding suggestive of excited delirium. However, it can be absent in sympathomimetic toxicity if the patient is volume depleted.

Diagnosis

Diagnosis is largely based on the clinical presentation and history. When the circumstances are unknown, the provider must exclude life-threatening, treatable etiologies, such as an intracranial hemorrhage, status epilepticus, or CNS infection. Urine drug screens are frequently performed, but they are fraught with false positives and negatives. Furthermore, a positive finding on a urine drug screen may be the result of a prior exposure and is not the cause of the patient's current symptoms. A basic metabolic panel should be obtained. Hyponatremia has been known to occur in 3,4-methylenedioxymethamphetamine ingestions causing status epilepticus.

TABLE 133.10 Xenobiotics Associated With Myopathy

Xenobiotic Category	Specific Agents
Antiretrovirals	Azidothymidine, zidovudine
Antibiotics	Penicillin, D-penicillamine, rifampin, sulfonamides
Antimalarials	Chloroquine, hydroxychloroquine
Lipid-lowering medications	Clofibrate, HMG-CoA reductase inhibitors (statins), niacin
Immunosuppressives and antineoplastics	Cyclosporine, vincristine, glucocorticoids (especially when combined with a neuromuscular blocker)
Other medications	Amiodarone, cimetidine, colchicine, doxylamine, ε-aminocaproic acid, ipecac, procainamide, propylthiouracil, suxamethonium (succinylcholine)
Recreational drugs	Ethanol, heroin, phencyclidine
Envenomations	Snakes: *Bothrops asper* (pit viper), *Agkistrodon* (pit viper), *Acanthophis* (elapid snakes), other crotaline snakes Spider: *Loxosceles* species (recluse spider)

Abbreviation: HMG-CoA, hydroxymethylglutaryl-coenzyme A.

Treatment

Treatment is largely supportive. Agitation should be treated with liberal *benzodiazepine* administration with the goal of minimizing muscle activity to prevent hyperthermia. Antipsychotics are not typically used to avoid administering drugs with anticholinergic actions that may increase the risk for seizures, delirium, and hyperthermia. If they are used, the *butyrophenones* (haloperidol, droperidol) are the best option, so long as the patient's QTc interval is normal. Antiepileptics are best avoided because these patients frequently have electrolyte abnormalities and are at higher risk for complications when they are given. Benzodiazepines, propofol, or barbiturates are preferred for seizure management. Hyperthermia must be avoided or rapidly corrected. IV hydration should be provided to prevent

TABLE 133.11 Smells and Odors Suggestive of Neurotoxic Xenobiotics

Odor or Smell	Xenobiotic
Mothballs	Camphor
Garlic	Organophosphates, arsenic, thallium
Peanuts	Vacor
Carrots	Cicutoxin (water hemlock)
Wintergreen	Methyl salicylates
Fruity	Chlorinated hydrocarbons
Glue	Solvents, toluene
Rotten eggs	DMSA, hydrogen sulfide
Shoe polish	Nitrobenzene

Abbreviation: DMSA, meso-2,3-dimercaptosuccinic acid.

rhabdomyolysis-induced kidney injury and hyperkalemia. Cocaine-induced wide complex tachycardia may be treated with sodium bicarbonate. Persistent hypertension despite adequate sedation can be treated with *phentolamine* 5 mg IV repeated as needed or nitroglycerine IV 5 to 20 μg/min. β-Blockers are best avoided given the potential for worsened vasospasm due to unopposed α-agonist activity. With optimal acute management, outcomes are typically outstanding.

TABLE 133.13 Neurotoxins and Their Antidotes/Specific Treatments

Neurotoxin/Toxidrome	Antidote/Treatment
Arsenic, lead, mercury	Dimercaprol (BAL)
TCAs	Bicarbonate
Rattlesnake envenomation	CroFab antivenin
Serotonin syndrome	Cyproheptadine
Arsenic, lead, mercury	D-Penicillamine
NMS, sympathomimetic hyperpyrexia	Dantrolene
Iron	Cefuroxime
Digoxin	Digoxin-specific Fab
Lead	DMSA, EDTA
Methanol, ethylene glycol	Ethanol
Benzodiazepines	Flumazenil
Methanol, methotrexate	Folate/folinic acid
Ethylene glycol, methanol	Fomepizole
Cyanide, hydrogen sulfide	Hydroxycobalamin, sodium thiosulfate, sodium nitrite
Local anesthetics, TCAs	Intralipid 20%
Valproic acid	L-Carnitine
Black widow spider envenomation	Lactrodectus antivenin
Opioids	Naloxone
Anticholinergics	Physostigmine
Organophosphates, carbamates	2-PAM
Isoniazid, monomethylhydrazine, ethylene glycol	Pyridoxine

Abbreviations: 2-PAM, pralidoxime; BAL, British anti-Lewesite; DMSA, meso-2,3-dimercaptosuccinic acid; EDTA, ethylenediaminetetraacetic acid; NMS, neuroleptic malignant syndrome; TCAs, tricyclic antidepressants.

Cholinergic Toxicity: Organophosphates and Carbamates

Organophosphates (OPs) and carbamates are AChE inhibitors that have been recognized and used since the mid-19th century. OPs are used as weapons of war (eg, sarin gas), insecticides, and for medicinal purposes. Carbamates have medical applications (eg, physostigmine) and are used as insecticides. Some xenobiotics that are carbamates do not inhibit AChE.

Epidemiology

Exposure to OPs and carbamates has been on the decline in the United States, falling to less than 10,000 reports per year in the mid-2000s. This is in contrast to the hundreds of thousands of deaths that occur each year in rural Asia. Chronic and delayed sequelae are subject to underreporting because the association between the exposure and clinical event may go unrecognized.

Pathobiology

OPs and carbamates are highly lipophilic xenobiotics that penetrate tissues with ease. Systemic toxicity occurs following dermal exposure via cutaneous absorption, inhalation, or less commonly, ingestion. The initial binding of AChE by OPs is reversible and then becomes irreversible, a process termed *aging*. The time to "aging" varies by OP and ranges from a few hours to a couple of days, with the weapons of war having the shortest time to aging. Once the bond is "aged," the antidote *pralidoxime* is not effective. Carbamates, on the other hand, do not age, and their effects dissipate upon their clearance.

Clinical Features

The clinical manifestations of OP or carbamate exposure are the result of increased acetylcholine in all neuronal junctions (ie, parasympathetic and sympathetic postganglionic muscarinic, parasympathetic and sympathetic preganglionic nicotinic, CNS, and NMJ nicotinic; Fig. 133.1). Symptom onset ranges from a few minutes to several hours. The high lipophilicity of the compounds causes them to be absorbed in adipose tissues; delayed effects can be seen when they diffuse into the circulation. A syndrome of OP-induced delayed axonal neuropathy is the result of inhibition of a neuronal lysophospholipase neuropathy target esterase.

Clinical full range of manifestations of OP or carbamate exposure are summarized in Table 133.15. The most common presentation includes miosis, diaphoresis, and dyspnea due to bronchorrhea. CNS manifestations range from restlessness and confusion to stupor, coma, and seizure activity. The increased acetylcholine at the NMJ leads to muscle fasciculations, weakness, and finally, paralysis. A syndrome of delayed NMJ dysfunction seen in 25% of patients 1 to 4 days after OP exposures, characterized by muscle weakness without fasciculations and respiratory insufficiency, has been called *intermediate syndrome*. Some patients experience an OP-induced delayed polyneuropathy that involves the upper and lower motor neurons days to weeks after exposure.

Diagnosis

The diagnosis of OP/carbamate toxicity is best made based on known exposure and subsequent symptoms. In cases of uncertain exposure or atypical or subtle presentations, measurement of plasma and red blood cell *cholinesterase levels* can assist in the diagnosis. There are several caveats to their interpretation that

TABLE 133.14 Clinical Findings of Neurotoxic Syndromes

Anticholinergic	• Flushed skin • Anhidrosis • Dry mucus membranes • Urinary retention • Constipation/ileus/decreased bowel sounds • Hyperthermia • Mydriasis • Blurred vision (impaired accommodation) • Agitation, confusion, delirium, psychosis • Visual hallucinations • Myoclonus, choreoathetosis, picking behavior • Stupor/coma (higher doses) • Seizures (very rarely status epilepticus)
Sympathomimetic	• Diaphoretic • Hypertensive • Tachycardic • Hyperthermia • Agitation, combativeness, psychosis • Hallucinations • Mydriasis • Seizures
Organophosphate and carbamate toxicity	• Restlessness • Diarrhea • Lacrimation • Salivation • Urination • Bronchorrhea
Organophosphate and carbamate toxicity *(continued)*	• Diaphoresis • Muscle fasciculations • Seizures/convulsions • Confusion to stupor/coma • Blurred vision/miosis[a] • Bronchospasm[a] • Bradycardia[a] • Hypotension[a]
Neuroleptic malignant syndrome	• Confusion/delirium • Catatonia/mutism • Stupor/coma • Lead pipe rigidity • Hyperthermia • Tachycardia • Hypertension • Tachypnea
Serotonin syndrome	• Agitation, hypervigilance • Confusion, delirium • Hyperthermia • Tachycardia • Hypertension • Diaphoresis • Diarrhea • Ocular clonus • Mydriasis • Akathisia • Tremor • Rigidity • Hyperreflexia[b] • Clonus[b]

[a]Cholinergic activity at the preganglionic sympathetic fibers leads to increased release of norepinephrine at the postganglionic nerve terminals in the target organs. Clinically, this results in activation of the sympathetic and parasympathetic pathways, which may lead to normocardia, tachycardia, normotension, bronchodilation, or mydriasis.
[b]More pronounced in the lower extremities.

TABLE 133.15 Xenobiotics With Anticholinergic Properties

Category	Specific Agents
Antihistamines	Cetirizine, chlorpheniramine, cimetidine, diphenhydramine, doxylamine, hydroxyzine, loratadine, ranitidine
Antipsychotics	Chlorpromazine, clozapine, olanzapine, quetiapine, risperidone, ziprasidone
Antiemetics	Doxylamine, metoclopramide, promethazine, scopolamine
Antivertigo	Meclizine, scopolamine
Tricyclic antidepressants	Amitriptyline, desipramine, doxepin, imipramine, nortriptyline
Antidepressants	Mirtazapine, paroxetine
Antiparkinsonian	Benztropine, biperiden, carbidopa/levodopa, procyclidine, selegiline, trihexyphenidyl
Ophthalmic	Atropine, cyclopentolate, homatropine, tropicamide
Bronchodilators	Ipratropium, tiotropium
Antispasmodics	Dicyclomine, hyoscyamine, loperamide, oxybutynin,[a] propantheline
Muscle relaxants	Baclofen, carisoprodol, cyclobenzaprine, methocarbamol
Others	Amantadine, glycopyrrolate,[a] trazodone
Botanicals	Deadly nightshade (atropine, *Atropa belladonna*), henbane (*Hyoscyamus niger*), jimson weed (scopolamine, *Datura stramonium*), mandrake (*Mandragora officinarum*)

[a]Does not cross blood-brain barrier.

TABLE 133.16 Xenobiotics Causing Sympathomimetic Toxicity/Acute Excited State

Category	Source	Specific Agents	Comments
Cocaine	Coca plant (*Erythroxylum coca*)	Cocaine hydrochloride, methylecgonidine, and ecgonidine ("crack")	WCT/arrhythmias and local anesthetic due to Na channel blockage
Methamphetamines	Synthetic	"Crank," "crystal," "chalk," "ice," etc	Lead toxicity can be seen due to contamination.
Designer (recreational) amphetamines	Synthetic	MDMA ("ecstasy," "XTC," or "Adam"), MDA, MDEA ("Eve"), PMA ("death"), DOM ("STP"), DOI, DOB, others	Hyponatremia not uncommonly seen that may be due to ADH-like action with MDMA; irreversible damage to serotoninergic neurons seen on MRI
Prescription amphetamines	Synthetic	Dextroamphetamine, lisdexamfetamine	
Prescription piperazine compounds	Synthetic	Methylphenidate	
NMDA receptor antagonists	Synthetic	PCP, ketamine, dextromethorphan	
Synthetic cannabinoid	Synthetic	HU-210, JWH-018, JWH-073, JWH-200, CP-47, and cannabicyclohexanol (all largely referred to as *K2* or *spice*)	New compounds rapidly cycled in as DEA adds them to controlled substances lists
Ephedrine	Ephedra (*ma-huang*)	Various recreation, herbal, and weight loss compounds	
Cathinone	Khat (*Catha edulis*)	Consumed by chewing or in teas	Manganese toxicity from contamination has produced EPS.
Cathinone derivatives	Synthetic	Mephedrone, methylone, ethylone, butylone, pyrovalerone, MDPV, methcathinone, ethcathinone, others ("bath salts" marketed under many names)	
Methylxanthines	*Coffea arabica*, many other botanicals	Caffeine	
N-substituted piperazine compounds	Synthetic	"Legal E," "legal X," BZP ("A2"), TFMPP ("Molly"), CPP, 25I-NBOMe ("N-bomb")	
Mescaline	Cacti (*Lophophora williamsii*, *Lophophora diffusa*, *Trichocereus pachanoi*)	"Peyote"	
LSD	Synthetic		
LSD-like substances	Hawaiian baby woodrose (*Argyreia nervosa*), Hawaiian woodrose (*Merremia tuberosa*), morning glory (*Ipomoea violacea*), ololiuqui (*Rivea corymbosa*)		
Hallucinogen: tryptamines (indole alkaloids)	*Psilocybe*, *Panaeolus*, and *Conocybe* mushrooms Various plants and organisms Synthetics	Psilocybin and psilocin "magic mushrooms" DMT, 5-MeO-DMT AMT, DiPT, 5-MeO-DiPT ("foxy" or "foxy-methoxy")	Drank as *ayahuasca*
Hallucinogens: botanicals	*Salvia divinorum* *Mitragyna speciosa* Korth tree African rain forest shrub (*Tabernanthe iboga*) Wormwood tree extract (*Artemisia absinthium*) Isoxazole mushrooms (*Amanita muscaria*, *Amanita pantherina*, *Amanita gemmata*, and *Amanita cothurnata*)	Salvinorin A or divinorin A Kratom, specific compound uncertain, suspect mitragynine Iboga (ibogaine) Thujone ("absinthe") Ibotenic acid and muscimol	Ion channel effects; 11 deaths reported from cardiac arrest Inhibitor of $GABA_A$ receptor→ seizures

Abbreviations: 25I-NBOMe, 2-(4-iodo-2,5-dimethoxyphenyl)-*N*-[(2-methoxyphenyl)methyl]ethanamine; 5-MeO-DiPT, 5-methoxy-tryptamine; 5-MeO-DMT, 5-methoxy-dimethyltryptamine, diisopropyl; ADH, alcohol dehydrogenase; AMT, alpha-methyltryptamine; BZP, 1-benzylpiperazine; CPP, 1-(chlorophenyl) piperazine; DEA, Drug Enforcement Administration; DiPT, diisopropyltryptamine; DMT, dimethyltryptamine; DOB, 2,5-dimethoxy-4-bromoamphetamine; DOI, 2,5-dimethoxy-4-iodoamphetamine; DOM, 4-methyl-2,5-dimethoxyamphetamine; EPS, extrapyramidal symptoms; $GABA_A$, γ-aminobutyric acid type A; LSD, lysergic acid diethylamide; MDA, 3,4-methylenedioxyamphetamine; MDEA, 3,4-methylenedioxymethamphetamine; MDMA, 3,4-methylenedioxymethamphetamine; MDPV, methylenedioxypyrovalerone; MRI, magnetic resonance imaging; Na, sodium; NMDA, *N*-methyl-D-aspartate; PCP, phencyclidine; PMA, paramethoxyamphetamine; STP, serenity, tranquility, and peace; TFMPP, 1-(trifluoromethylphenyl)piperazine; WCT, wide complex tachycardia.

FIGURE 133.1 Sites of action of organophosphates and carbamates. Abbreviations: ACh, acetylcholine; NE, norepinephrine.

are beyond the scope of this text. Spontaneous repetitive potentials on single-nerve electromyography are a sensitive finding of AChE inhibition.

Treatment

Patients with OP exposure must be rapidly decontaminated by removing all clothing and liberally irrigating the skin. The initial treatment begins with liberal amounts of *atropine* (starting dose 1-2 mg IV doubled every 5 min until respiratory secretions are ceased). It is not uncommon for patients to require nearly 500 mg of atropine during the initial hour of care. Additionally, an oxime, typically *pralidoxime*, should be administered as soon as the syndrome is suspected (1-2 mg IV every 4 h for at least 24 h) to prevent aging and irreversible inhibition of AChE. Of note, the evidence supporting oxime use is conflicting. Benzodiazepines, particularly *diazepam* 5 to 10 mg IV every 4 to 6 hours, have been observed to decrease cerebral injury resulting from OP-induced seizures and mitigate OP-induced respiratory depression. *Ketamine* (1-4 mg/kg loading dose followed by 0.1-0.5 mg/min IV infusion) and other *N*-methyl-D-aspartate receptor antagonists have been shown to reduce OP-induced seizures and enhance survival in mice. When endotracheal intubation is being performed, succinylcholine is best avoided.

Outcome

The case fatality rate ranges from 10% to 40%. Evidence is lacking that describes neurologic outcomes with precision following acute and chronic poisoning. Residual deficits with an incomplete recovery are common in those with OPIDN. Cognitive deficits have been observed after acute OP exposure.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is an idiosyncratic life-threatening neurologic emergency seen in those on neuroleptic (antidopaminergic) agents or after withdrawal of dopaminergic medications (Table 133.17). Precise estimates of its incidence are lacking. It can occur at any age of life and is seen more often in men, but this is proportional to the increased use of neuroleptics in the male gender. NMS is frequently seen within the first 2 weeks of treatment with a neuroleptic, but it may occur at any time even in those on antipsychotics for years. The risk of NMS is higher with rapid dose escalation, parenteral administration, switching of agents, and when higher doses are used. The precise pathophysiology is not known, but it is believed to be the result of a relative dopamine deficit in the CNS. Genetic studies have identified a specific allele of the D2 receptor that results in a decreased amount and function of dopamine receptors to be a risk factor.

TABLE 133.17 Examples of Medications That Cause Neuroleptic Malignant Syndrome

Dopaminergic Agents (Discontinuation)	Antipsychotics	Antiemetics
Bromocriptine	Aripiprazole	Droperidol
Amantadine	Chlorpromazine	Metoclopramide
Rimantadine	Clozapine	Prochlorperazine
Memantine	Haloperidol	Promethazine
Levodopa	Olanzapine	
Cabergoline	Quetiapine	
Dihydroergocryptine	Risperidone	
Pergolide	Thioridazine	
	Ziprasidone	

Clinical Features

Clinical features include mental status changes, muscular rigidity, hyperthermia, and autonomic dysfunction; symptoms typically present in this sequence. Mental status changes may precede the other symptoms by 24 hours or more. Mental status changes range from confusion and delirium to catatonia, mutism, stupor, and coma. Cogwheeling, dystonia, and other dyskinesias can be seen in addition to the lead pipe rigidity. The majority of patients will have a temperature higher than 38°C, with nearly half exceeding 40°C. Autonomic dysfunction manifests as tachycardia, hypertension, and tachypnea. Laboratory abnormalities may include an elevated creatine kinase (>4 times normal), transaminitis, and leukocytosis.

Diagnosis

The diagnosis is clinical. A scoring system has been proposed, but it has not been validated. The evaluation is typically targeted toward identifying metabolic derangements that require correction and the exclusion of other differential diagnoses. Cerebral edema has been observed on magnetic resonance imaging (MRI). Seizures are not typically seen in NMS. Cerebral spinal fluid evaluation may reveal a mild protein elevation without pleocytosis or hypoglycorrhachia.

Treatment

Treatment includes aggressive supportive therapy, temperature correction, and cessation of any possible offending agent (or resumption of a discontinued one). *Dantrolene* (1-2.5 mg/kg IV), a skeletal muscle relaxant that works by inhibiting calcium release from the sarcoplasmic reticulum, maybe used to reduce rigidity and help to correct hyperthermia and rhabdomyolysis. It should not be used if there is a significant transaminitis. *Amantadine* (100 mg orally every 12 h) and *bromocriptine* (2.5 mg

orally every 6 h) are dopamine agonists that may be considered in the treatment of NMS. Summated evidence from retrospective observations and cases suggests that they may hasten recovery and reduce mortality, but this is far from conclusive. There are reports of electroconvulsive therapy being used, but its true efficacy is far from clear. In fact, several patients are reported to have gone into cardiac arrest during electroconvulsive therapy.

Outcome

Recovery typically occurs within 2 weeks of stopping the neuroleptic (or resuming the dopamine agonist), with some exceptions being reported. The mortality ranges from 5% to 20%. Relapse upon resumption of neuroleptics is very difficult to predict. If they must be resumed, lower potency agents should be selected at the lowest possible dose. Weak evidence suggests lithium therapy may increase the risk of developing NMS; therefore, it is best avoided if possible.

Serotonin Syndrome

Serotonin syndrome is a life-threatening neurologic emergency resulting from a relative serotonin excess. The death of Libby Zion at New York Hospital in 1984, which was reported in the mainstream media and eventually led to the creation of the contemporary laws that limit resident work hours, was suspected to be the result of serotonin syndrome. The syndrome can be precipitated when two or more serotonergic medications are coadministered but can occur with monotherapy as well (see **Table 133.18** for a list of serotonergic xenobiotics). There are over 25,000 reported cases of potential toxic exposure to serotonergic agents annually in the United States, with nearly 10,000 of them suspected to cause serotonin syndrome resulting in nearly 100 deaths. Serotonin syndrome occurs on a spectrum. Mild symptoms are likely to go unrecognized and are underreported.

Pathobiology

Serotonin receptors are primarily found in the CNS in the brainstem (midline raphe nuclei) and peripherally in the gastrointestinal tract, vasculature, and platelets. Rapid increases in serotonin concentration at these sites produce the symptoms of serotonin syndrome. Mild symptoms include tremor, diarrhea, and restlessness or hypervigilance. More severe symptoms result in further autonomic dysfunction, hyperthermia (>40°C), and more significant deficits in mental status (see **Table 133.14**). Clonus (ocular, spontaneous, and induced) and hyperreflexia are specific for serotonin syndrome and are more pronounced in the lower extremities. The onset is typically within minutes to hours of exposure to the serotonergic agent.

Diagnosis

Table 133.19 outlines the Hunter Serotonin Toxicity Criteria, which have a sensitivity of 84% and specificity of 97% for diagnosing serotonin syndrome. The diagnosis is completely clinical. Laboratory and imaging investigations are done to evaluate for metabolic derangements and to exclude alternative diagnoses.

Management

Symptoms resolve promptly upon the cessation of all serotonergic agents, making this the cornerstone of treatment. Unfortunately, some selective serotonin reuptake inhibitors have long half-lives (eg, fluoxetine's half-life is 1 wk). In such cases, prolonged supportive therapy is necessary. Agitation should be treated with benzodiazepines. If agitation persists or if autonomic dysfunction persists despite control of agitation, *cyproheptadine*, a histamine and serotonin antagonist, maybe used. It is only available for oral administration. The initial dose is 12 mg followed by 2 mg every 2 hours. There is little evidence beyond case reports to confirm that it has any therapeutic benefit. Outcomes can be expected to be excellent with optimal supportive care and prompt withdrawal of the serotonergic agent(s).

TABLE 133.18 Xenobiotics Known to Potentially Cause Serotonin Syndrome

Category	Specific Examples
SSRIs	Citalopram, escitalopram, fluoxetine, paroxetine, sertraline
SNRIs	Desvenlafaxine, duloxetine, milnacipran, venlafaxine
TCAs	Amitriptyline, clomipramine, desipramine, doxepin, imipramine, nortriptyline, protriptyline, trimipramine
MAOIs	Isocarboxazid, moclobemide, phenelzine, tranylcypromine
DNRIs	Bupropion
SARIs	Nefazodone, trazodone, and vilazodone
Recreational drugs	Cocaine, methamphetamine, designer amphetamines (eg, MDMA ["ecstasy"]; see Table 133.16), LSD
AEDs	Carbamazepine, valproate
Triptans	Almotriptan, eletriptan, frovatriptan, rizatriptan, sumatriptan, zolmitriptan
Ergots	Ergotamine, methylergonovine
Amphetamines	Dextroamphetamine, lisdexamfetamine
Opioids	Meperidine, tramadol, pentazocine, fentanyl
Appetite suppressants	Fenfluramine, phentermine, dexfenfluramine, sibutramine
Parkinson medications	Levodopa, carbidopa/levodopa, rasagiline, selegiline
Serotonin receptor antagonists	Dolasetron, granisetron, ondansetron, palonosetron
Antibiotics	Linezolid, tedizolid
Others	Tryptophan, St John's wort, cyclobenzaprine, dextromethorphan, buspirone, lithium, methylene blue, procarbazine

Abbreviations: AEDs, antiepileptic drugs; DNRIs, dopamine–norepinephrine uptake inhibitors; LSD, lysergic acid diethylamide; MAOIs, monoamine oxidase inhibitors; MDMA, 3,4-methylenedioxymethamphetamine; SARIs, serotonin antagonist and reuptake inhibitors; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

TABLE 133.19 Hunter Serotonin Toxicity Criteria

Any of the following are present after a serotonergic agent is introduced:
- Spontaneous clonus
- Inducible or ocular clonus with agitation or diaphoresis
- Inducible or ocular clonus with hypertonicity and fever
- Tremor with hyperreflexia

Carbon Monoxide Poisoning

Carbon monoxide (CO) intoxication is a common cause of neurotoxic damage and death. Deaths averaged 5,600 annually over a 10-year period in the United States and split between accidental and intentional. Statistics on nonfatal CO encephalopathy and the delayed CO-induced neuropsychiatric syndrome are imprecise. CO competes with oxygen for binding to hemoglobin, myoglobin, and cytochrome *c* oxidase resulting in tissue hypoxia and disordered cellular energy generation.

Clinical Features

Clinical presentations range from mild, viral syndrome–like symptoms, such as headache, malaise, dizziness, nausea, difficulty concentrating, and dyspnea, to coma, particularly in the setting of smoke inhalation. In survivors, neurologic symptoms include dementia, cerebellar dysfunction, and parkinsonism. A delayed neuropsychiatric syndrome may follow acute exposure by 3 to 240 days with cognitive and personality changes and psychotic behavior. This syndrome occurs in 10% to 30% of CO poisonings. Although up to 10% of victims show gross neurologic or psychiatric impairment, more frequently there is only a subtle, persistent neuropsychiatric deficit. Computed tomography, MRI, magnetic resonance spectroscopy, and isotopic imaging can disclose the brain damage. Postmortem findings include multifocal necrosis and myelinopathy with discrete lesions in the globus pallidus, cortex, and white matter.

Diagnosis

The diagnosis is made by measuring the serum carboxyhemoglobin (COHb) level. Normal levels are less than 5% in nonsmokers and can be as high as 12% in two-pack-per-day smokers. Although serious toxicity is often associated with levels greater than 25%, neurologic damage is not always directly related to the COHb level. Furthermore, serum levels may have fallen by the time the patient reaches the emergency department such that a normal COHb level does not rule out CO poisoning. Blood taken at the scene by emergency technicians can be used. Measurement of CO in expired air and in the exposure area's ambient air can also be useful. The U.S. government standard for CO prohibits exposure to more than 35 ppm, averaged over an 8-hour workday.

Treatment

Initial treatment is 100% oxygen by a nonrebreather face mask, which will reduce the elimination half-life of COHb from 4 to 5 hours to 1 to 2 hours. Treatment continues until the COHb levels are below 10%. Most experts advocate hyperbaric oxygen for treatment of symptomatic CO poisoning. It enhances elimination of COHb with an average half-life of 20 minutes at three atmospheres, but randomized trials have not clarified whether it hastens recovery or reduces the rate of late sequelae. Coma, ischemic symptoms, acidosis, levels over 25%, and pregnancy with levels over 20% are indications for hyperbaric oxygen.

Malignant Hyperthermia

Malignant hyperthermia is a life-threatening reaction that occurs in approximately 1/100,000 exposures to volatile anesthetics or succinylcholine. It results from the improper opening of the ryanodine receptors on the sarcoplasmic reticulum in skeletal muscle. Its presentation is on a spectrum, with the most pronounced episodes being characterized by diffuse muscle rigidity despite neuromuscular blockade. The first signs are an elevation of the end-tidal carbon dioxide and tachycardia. Fever develops later, with the temperature being prone to rapid elevations. Untreated, rhabdomyolysis and hyperthermia and their associated complications lead to death. Rapid treatment with *dantrolene* (2.5 mg/kg IV followed by 1 mg/kg IV until symptoms resolve) is the cornerstone of treatment.

Epidemiologically, malignant hyperthermia is most commonly the result of a mutation of the ryanodine receptor or dihydropyridine receptor. Additional cases are seen in those with several hereditary myopathies. Population-based screening is not justifiable. Genetic testing is specific but not sensitive. Contracture testing is much more sensitive, but it is invasive and only available at select centers. Additionally, contracture testing has a 20% false-positive rate.

Strychnine Poisoning

Strychnine, a competitive antagonist of glycine, causes involuntary tonic-clonic activity in otherwise awake individuals. It is derived from the seeds of the tree *Strychnos* nux-vomica. Contemporary poisonings are usually the result of the adulteration of recreational drugs and less commonly in herbal medications. It is absorbed through all routes, including dermal, with an onset of 10 to 20 minutes. It is largely eliminated by the liver with a half-life of approximately 12 hours. The diagnosis is clinical. Rhabdomyolysis and its associated complications are a significant threat as well as respiratory arrest from an inability to properly ventilate. Treatment is supportive with benzodiazepine or propofol use.

Methanol (Methyl Alcohol)

Methanol ingestion occurs when it is substituted for ethanol or in suicide attempts. Poisoning is related to the conversion of methanol to formaldehyde and formic acid, which results in a severe metabolic acidosis. The initial clinical presentation is similar to acute ethanol intoxication with gastrointestinal symptoms, drunkenness, and coma. The mortality rate is approximately 35%. Visual loss is common and attributed to retinal metabolism of methanol to formic acid. Cerebral imaging has demonstrated petechial hemorrhages and edema. Inhibitors of aldehyde dehydrogenase (ethanol and fomepizole) block the conversion of methanol to formaldehyde, allowing it to be excreted in the urine.

Volatile Organic Compounds

Neurologic syndromes caused by volatile organic compounds (*solvents*) occur after either occupational or deliberate exposure by inhalation abuse. The agents include aromatic and aliphatic hydrocarbons, alcohols, esters, ketones, aliphatic nitrates, anesthetic agents, halogenated solvents, and propellants. Aromatic hydrocarbons, especially *toluene*, produce cerebral and cerebellar damage. Aliphatic hydrocarbons caused outbreaks of peripheral neuropathy in industrial or recreational exposures to *n*-hexane or methyl-*n*-butyl ketone, which begin in the lower extremities and ascend, resembling Guillain-Barré syndrome. Pathophysiologically, neurofilamentous axonal swelling and distal axonal degeneration are seen.

Other organic compounds that induce axonal neuropathy by industrial exposure are acrylamide, carbon disulfide, methyl bromide, and triorthocresyl phosphate. Halogenated hydrocarbons

are toxic for the CNS by damaging nerve cell membranes and altering neurotransmission; an excitatory phase is rapidly followed by CNS depression. The compounds include chloroform, methylene chloride, and tetrachloroethane. The neurotoxic potential of one substance is sometimes facilitated by others in the same commercial product.

Nitrous Oxide Myelopathy

Nitrous oxide (NO), commonly known as *laughing gas*, is used as an inhaled anesthetic. Chronic exposure to NO, also known as *Layzer syndrome*, was described in the late 1970s in a series of dentists with occupational exposure or chronic NO abuse. It has also been described in those with a vitamin B_{12} deficiency that are exposed to NO. Because NO interferes with the action of vitamin B_{12}, symptoms mimic its deficiency and include paresthesias, Lhermitte symptoms, ataxia, leg weakness, impotence, and sphincter disturbances. Examination showed signs of sensorimotor polyneuropathy, often implicating the posterior and lateral columns of the spinal cord, which can be confirmed on MRI. Electrodiagnostic tests showed axonal polyneuropathy. Animal studies have suggested that methionine has a protective role. Improvement has been reported to occur over weeks to months after exposure ceased.

Heavy Metals

Lead

Acute lead encephalopathy in children is typically attributed to pica or ingestion of flaking lead-containing paint. Children with blood levels above 80 μg/dL are more susceptible than adults to overt lead encephalopathy with delirium, ataxia, seizure, stupor, or coma with associated cerebral edema. Adults with chronic lead exposure yielding blood lead levels of 25 to 60 μg/dL may experience irritability, headache, myalgias, anorexia, nausea, crampy abdominal pain, and depression with signs of impaired visual-motor dexterity and reaction times. Objective neuropathies that manifest in muscle weakness and atrophy occur with long-term levels of 60 μg/dL or more. Because of links between lead and cognitive dysfunction, behavioral problems, as well as stunted growth in children, the Centers for Disease Control and Prevention has declared levels exceeding blood concentration of 5 μg/dL to be abnormal and requiring case management. Periodic screening of children aged 9 to 36 months is advocated, especially because the symptoms are nonspecific, including lethargy, anorexia, intermittent abdominal pain with vomiting, or constipation. Testing blood lead levels is recommended for children with presumed autism, attention deficit disorder, pervasive development disorder, mental retardation, or language problems.

A diagnosis of lead intoxication is supported if blood zinc protoporphyrin exceeds 100 μg/dL or if urinary aminolevulinic acid excretion is more than 15 mg/L. With blood lead levels of 10 μg/dL, the activity of aminolevulinic acid dehydratase is low. At higher lead levels, the activities of coproporphyrinogen oxidase and ferrochelatase are also low. Anemia and basophilic stippling of erythrocytes are characteristic. Nerve conduction velocities are nonspecifically slow in lead and other neuropathies.

Treatment combines decontamination, supportive care, and the judicious use of chelating agents. In affected people, chelation therapy commences with levels of 40 to 45 μg/dL. Supportive care may include treatment of increased intracranial pressure by standard use of IV mannitol and glucocorticoids, the latter because the pathophysiology of lead encephalopathy involves capillary leak. In patients with lead encephalopathy, calcium disodium edetate or calcium ethylenediaminetetraacetic acid should be administered at 30 mg/kg every 24 hours. Some advocate initiating chelation with a single dose of dimercaprol (British anti-Lewisite [BAL]) 4 to 5 mg/kg deep intramuscularly. Alternatively, meso-2,3-dimercaptosuccinic acid (succimer) is advocated for treatment of moderately severe chronic lead intoxication. Childhood lead exposure carries a risk of long-lasting health impairment, especially with neurocognitive and neurobehavioral sequelae, emphasizing the need for primary prevention and for obtaining occupational and environmental information.

Mercury

The relations between elemental, inorganic, and organic forms of mercury involve transformations from one form to another. Modern epidemics include Minamata disease from fish contaminated by methyl mercury (MeHg), which affected 2,500 people in Japan, and erethism (abnormal sensitivity to stimulation of any type)—also known as the *mad hatter syndrome*—from mercuric nitrate used in the hatting industry. Acute toxicity from elemental mercury may include encephalopathy and seizures, whereas its chronic toxicity includes peripheral sensorimotor neuropathy, dysarthria, and parkinsonism. Subclinical nerve conduction and neuropsychiatric abnormalities have been documented in the modern workplace.

Organic mercury includes MeHg, the cause of Minamata disease, and ethyl mercury. Excessive MeHg intake has been reported in fish-eating communities in Greenland, the Faroe Islands, the Seychelles, the Madeira Basin of the Amazon River, and New Zealand. Symptoms of organic mercury toxicity include tremor; ataxia; dysarthria; paresthesias of the hands, feet, and mouth; visual field constriction; erethism; and spasticity. Prenatal exposure to MeHg can cause severe congenital abnormalities such as micrognathia, microcephaly, mental retardation, blindness, and motor deficits. Minamata disease produces neuropathologic abnormalities in the cerebral cortex, cerebellum, and peripheral nerves.

The 24-hour urine mercury concentration may assess both recent exposure and elimination of tissue burden. The normal blood concentration is less than 10 to 20 μg/L, and the urinary level is less than 20 μg/L. Treatment consists of decontamination and chelation with established guidelines. If the person is symptomatic, dimercaprol is given intramuscularly 3 to 5 mg/kg every 4 hours on day 1, every 12 hours on day 2, and then once a day for the next 3 days followed by a 2-day interruption. Other agents are meso-2,3-dimercaptosuccinic acid and 2,3-dimercapto-propane-1-sulfonate, a water-soluble form of BAL. All agents are somewhat effective for organic and inorganic mercury poisoning.

Arsenic

Arsenic toxicity is a global health problem. It is estimated that tens of millions of people, for example, in Bangladesh, are at risk for excessive arsenic levels from natural geologic sources leaching into aquifers, contaminated drinking water, mining, and other industrial processes. Arsenicosis can result in cancer at various sites, encephalopathy, and axonal peripheral neuropathy. The chronic version is "blackfoot disease" with

vascular changes, gangrene, and a less severe peripheral neuropathy. The use of arsenic trioxide to treat leukemia may cause arsenic neuropathy.

Vomiting, bloody diarrhea, myoglobinuria, renal failure, arrhythmias, hypotension, seizures, coma, and death characterize acute arsenic poisoning. In survivors, *Mees lines* on the fingernails and sensorimotor neuropathy appear in 7 to 14 days. Slow and incomplete recovery takes years. Cognition may be impaired in some survivors depending on the severity of the acute encephalopathy.

The diagnosis of arsenic intoxication is confirmed by urinary levels more than 75 μg/dL. Hair analysis has been used but is not reliable. BAL therapy is also used for acute arsenic poisoning. It is most effective before symptoms of neuropathy appear. BAL is considered more effective than penicillamine in treating the chronic neuropathy. Hemodialysis is another treatment for an acute episode.

Thallium

Despite the ban on manufacture of thallium rodenticides in the United States, accidental and suicidal exposures still occur because the poisons are available in other countries. After an acute exposure, gastrointestinal symptoms occur first with paresthesias occurring a few weeks later with the onset of a neuropathy. The encephalopathy presents with cognitive impairment and choreoathetosis, myoclonus, or other involuntary movements. Alopecia, which is unique to thallium toxicity, begins 1 to 3 weeks after exposure.

After acute exposure, blood tests are not useful for detecting thallium because it is rapidly taken up by the cells. Normal urinary thallium values are 0.3 to 0.8 μg/L. Levels of 200 to 300 μg/L are seen in overt poisoning. A provocative test uses potassium chloride, which is given orally in a dose of 45 mEq. Potassium displaces thallium from tissue stores, blood levels rise, and urinary content can be followed serially.

Treatment of acute poisoning depends in part on enhancing urinary and fecal excretion of thallium by giving laxatives and using Prussian blue or activated charcoal to retard absorption. Urinary excretion is enhanced by forced diuresis and administration of potassium chloride. Hemodialysis may be effective.

Manganese

Manganese intoxication, still a threat in industrial settings, reproduces the essential motor features of parkinsonism but with sufficient clinical and pathologic differences to indicate the conditions are not identical; for instance, exaggerated tendon reflexes and behavioral features occur early in manganese toxicity. The outlook is gloomy, including severe cognitive loss. Responses to levodopa and to chelation therapy are limited.

Aluminum

Dialysis dementia (see Chapter 125) has been attributed to aluminum in the dialysis water and also in ingested phosphate binders used to control blood phosphorus levels. Treatment of the water and avoidance of the binders have decreased the incidence. Encephalopathy, however, has also occurred in uremic patients dialyzed with deionized water and also in those that ingest the phosphate binders without dialysis. Paresthesias and weakness were part of "potroom palsy," a complex syndrome in workers in a smelter who were exposed to pots that had not been vented properly. Other manifestations included ataxia, tremor, and memory loss.

Plant, Animal, and Marine Neurotoxins

Ciguatera poisoning or the *marine neurotoxic syndrome* is the most common nonbacterial form of food poisoning in the United States and is endemic in subtropical regions. Toxins are found in tropical reef fish, which acquire them when they consume dinoflagellates. Initial symptoms are gastrointestinal followed by sensory symptoms, paresthesias, and pruritus. *Sensory inversion*, manifested as cold feeling hot and vice versa, dysuria, and dyspareunia are particular to this poisoning. Myalgia, fasciculations, areflexia, trismus, and carpopedal spasm are also reported. Respiratory failure is uncommon. There is no formal laboratory or clinical criteria for diagnosis. Mechanistically, most associated toxins open sodium channels. Treatment is symptomatic, with a randomized trial of mannitol showing no advantage.

Shellfish poisoning can result from contamination of mollusks by saxitoxin, which blocks sodium channels. The symptoms are similar to ciguatera but more severe, and respiratory depression is a greater risk. Cerebellar ataxia was the dominant finding and hypertension is common. Binding assays and liquid chromatography identify the toxin in serum and urine. In Japan, the agent of puffer fish poisoning is tetrodotoxin. Treatment of these conditions is symptomatic.

Amnesic shellfish poison is due to consuming domoic acid, a glutamate receptor agonist, in mussels, which can result in a transient encephalopathy. There is no specific treatment.

Many plants contain pharmacologically active substances that cross the blood-brain barrier with resulting delirium, hallucinations, seizures, and sedation. *Cicutoxin*, from *water hemlock*, produces a clinical state of agitation and confusion followed by sedation. *Andromedotoxin* from *rhododendron* is a depressant. Over 100,000 potential toxic exposures to botanicals are reported per year.

Neurolathyrism presents with spastic paraparesis in impoverished countries and is seen during times of drought when the *Lathyrus* plant is consumed. *Konzo* is a disease due to prolonged consumption of the bitter cassava *Manihot esculenta* prevalent in sub-Saharan Africa with a similar presentation. Cassava contains a cyanoglucoside linamarin, which is enzymatically converted to cyanide, which then damages neural calls. The clinical picture is a sudden, symmetric, and permanent spastic paraplegia. Males are predominately affected in both conditions. Hearing loss, visual impairment, and dysarthria may be seen in cassavaism but not neurolathyrism.

Radiation Injury 134

Matthew R. Leach and Christopher Zammit

KEY POINTS

1. The clinical effects of radiation are related to individual patient susceptibility, dose absorbed, dose rate, and distribution of dose.
2. Radiation necrosis may be differentiated from brain tumor disease progression by higher apparent diffusion coefficient (ADC) values on diffusion imaging, hypermetabolism on positron emission tomography, reduction in choline levels on magnetic resonance single-photon emission computed tomography, and/or hypoperfusion on magnetic resonance perfusion imaging.
3. First-line treatment for radiation necrosis is glucocorticoids. Refractory cases may be treated with bevacizumab, hyperbaric oxygen, or surgery.
4. Late manifestations of radiation injury are generally less responsive to treatment and often permanent, such as myelopathy and delayed radiation necrosis.

INTRODUCTION

The first known description of nervous system injury by radiation was in 1930 by Fischer and Holfelder. Contemporary medicine's use of radiotherapy to treat malignancies has brought radiation injury into daily clinical discussion. The expansion of nuclear energy programs during the 1970s increased the risk for widespread radiation injury in the event of nuclear plant failure. The Three Mile Island accident in 1979 and disasters at the Chernobyl Nuclear Power Station in 1986 and the Fukushima Nuclear Power Plant following a tsunami in 2011 have provided real reminders of the ongoing risk.

Radiation injury is the result of exposure to ionizing radiation. Nonionizing radiation does not cause neurologic injury; its biologic injury is limited to thermal surface injury. Nervous system injury results from x-rays or γ rays; alpha and beta particles also produce ionizing radiation, but they do not penetrate tissue by more than 8 mm and therefore do not reach the central or peripheral nervous system. Internal injury can result when alpha or beta particles are ingested, but even in such cases, their proximity to central neurologic structures limits their ability to produce significant neurologic injury.

The amount of radiation absorbed is described in terms of *gray* (Gy), where 1 Gy is equal to 1 J of radiation absorbed per kilogram of tissue. A *radiation-absorbed dose* (rad) is equal to 100th of a Gy (ie, 100 rad = 1 Gy). One rad is also equal to one *roentgen equivalent man* (rem), that is, 1 rad = 1 rem. In contrast, the dose of radiation delivered is described in sieverts (Sv), where 1 Sv is equal to 100 rem. To provide context, we are exposed to approximately 3 millisieverts (mSv) per year from natural radioactive material and cosmic radiation. Furthermore, one head computed tomography (CT) delivers 2 mSv of radiation.

Therapeutic radiation is typically administered as whole brain radiation therapy (WBRT) or stereotactic radiosurgery (SRS). WBRT is diffuse irradiation of the entire brain (although many new protocols are "temporal" or "hippocampal sparing" to reduce cognitive side effects) and is used either prophylactically or for treatment of diffuse metastases. In contrast, SRS focuses radiation on specific lesions, converging many low-dose beams of radiation on a target with millimeter precision to deliver high-dose radiation at their intersection with relatively little effect on surrounding tissues. Radiation effects on the nervous system and other organ systems (Table 134.1) can be difficult to predict because the amount of radiation delivered is not necessarily equal to the amount absorbed, particularly when considering occupational or environmental exposures. The clinical effects of radiation are related to the individual susceptibility, dose rate, dose absorbed, and distribution of the dose.

EPIDEMIOLOGY

As mentioned earlier, the incidence of radiation injury is related to individual patient characteristics, use of concomitant therapies, the dose amount, dose rate, and distribution of the exposure (Table 134.2). In particular, patients at the extremes of age are more at risk for complications with radiotherapy and complications increase with concomitant administration of many chemotherapies. Hypertension and diabetes mellitus increase the

TABLE 134.1 Radiation Effects

- Acute constitutional symptoms: fatigue, malaise, anorexia, nausea
- Acute cerebral edema
- Early-delayed leukoencephalopathy or demyelination
- Late-delayed radiation necrosis
- Myelopathy
- Vasculopathy
- Stroke-like migraine attacks after radiation therapy (SMART) syndrome
- Plexopathy
- Neuropathy (including cranial and optic neuropathy)
- Ocular neuromyotonia
- Neuroendocrine disorders
- Radiation-induced tumors
- Neuropsychiatric, behavioral, and cognitive disturbances

TABLE 134.2 Risk Factors for Injury After Radiation Exposure

• Age <5 y or >60 y
• Use of concomitant chemotherapy
• Extent of radiation bed
• Total radiation dose
• Fractionation schedule

risk of radiation injury in adults. Radiation injury to the nervous system may occur after scalp radiation for tinea capitis, radiotherapy to the head or neck for extracranial malignancy, whole body radiation for liquid malignancies or stem cell transplant, brachytherapy, or both WBRT and SRS for intracranial malignancies. The majority of patients undergoing radiation therapy for central nervous system malignancy will experience some form of side effect, but the duration and severity of these effects vary widely.

Acute cerebral edema may occur days to weeks after radiation. It rarely occurs at doses below 2 Gy and is seen in about half of the time after doses over 7.5 Gy. Delayed leukoencephalopathy and/or demyelination typically occur between 1 and 6 months after exposure. Radiation necrosis is seen between 6 months and 7.5 years after radiotherapy, with a median onset of 14 months, and 75% of patients experience symptoms within 3 years. The cumulative dosing threshold for necrosis is reported as being 50 to 60 Gy, with a 5% incidence in those receiving a total of 50 Gy in daily doses of 2 Gy.

Myelopathy occurs 1 to 3 years after radiation, with peaks in incidence at 12 to 14 months and 24 to 28 months. Similar to radiation necrosis, 5% of patients receiving total doses of approximately 60 Gy to the spinal cord have been reported to develop myelopathy, but this is not consistent.

Intracranial and extracranial vasculopathy have been seen over 20 years after radiation exposure. Patients treated with radiotherapy incur significantly increased morbidity and mortality due to cerebrovascular disease compared to the general population with some reviews citing up to a fourfold increase. Incidence increases with increasing doses of radiation. Stroke-like migraine attacks after radiation therapy (*SMART*) syndrome has been reported many years after whole brain radiation. It is rare with risk factors that include time since irradiation, male sex, and genetic susceptibility.

Plexopathy and neuropathy (including cranial and optic neuropathy) are typically seen after radiation directed at the affected region. Brachial plexopathy after radiation for breast cancer has a median onset of 4.5 months. Transient symptoms are seen in 1% to 2% of those receiving doses of 50 Gy. Lumbosacral plexopathy is rarely seen, even at doses of up to 70 to 80 Gy. Neuropathy is rarely seen at doses under 60 Gy. Optic neuropathy is seen within 3 years of exposure when it occurs.

The radiation dose threshold associated with neuroendocrine disorders in children is less than that for the previously mentioned injuries. Growth hormone deficiency is seen in fractionated doses of less than 20 Gy. Sixty-five percent of children undergoing prophylactic cranial radiation for acute lymphocytic leukemia in a total dose of 20 to 30 Gy are observed to have a growth hormone deficit. Other neuroendocrine disorders occur at total doses over 40 to 50 Gy, including gonadotropin deficiency, thyrotropin deficiency, adrenocorticotropic hormone deficiency, and hyperprolactinemia. In total, an estimated 50% of survivors of childhood cancer will develop an endocrinopathy, with most patients needing lifelong follow-up with an endocrinologist.

Cognitive and neuropsychiatric disturbances are all too common in children receiving radiation for malignancies, with some series reporting rates of 100%. Similarly, almost all adults undergoing WBRT will experience cognitive side effects. Radiotherapy that traverses the hippocampus or frontostriatal brain circuitry is felt to increase the risk of occurrence and many contemporary protocols are "hippocampal sparing" with radiation directed away from the mesial temporal area.

Radiation-induced tumors include meningiomas, sarcomas, gliomas, and schwannomas. Meningiomas have a latency of up to 37 years at doses of 8.5 Gy and as short as 18 months after 20 Gy. Sarcomas are seen about 10 years after doses of 50 Gy with an unclear frequency. The relationship between glioma occurrence and radiation therapy is not agreed on. However, high-volume cell phone use has been associated with the occurrence of gliomas (and meningiomas) and the risk appears to be related to the "dose" of cell phone use. Peripheral nerve tumors are seen in about 10% of patients receiving radiation therapy directed through a peripheral nerve.

PATHOBIOLOGY

Ionizing radiation causes biologic injury by damaging the most basic elements that make up cellular structures and conduct cellular processes. The x-rays and/or γ rays collide with electrons, causing elements to become ionized that were not otherwise, altering their ability to conduct cellular functions. This will damage DNA, leading to mutations that contribute to the increased malignancy risk. Cells that have high rates of turnover are the most vulnerable to this damage (eg, hematopoietic, mucosal, endothelial, and gastrointestinal cells). This is one of the reasons that the hippocampus, with its neural progenitor cell population, is particularly sensitive to radiation.

The acute side effects and early cerebral edema seen after radiation are suspected to be secondary to vascular endothelial dysfunction and disruption of the blood-brain barrier, causing vasogenic edema (hence its clinical response to corticosteroids). This endothelial damage also contributes to advanced/premature hyalinization of the vessel wall more chronically. The latently observed leukoencephalopathy is thought to be the result of this edema in combination with a transient demyelination due to oligodendrocyte dysfunction, as the time frame corresponds with expected myelin turnover.

Later effects are due to cell death related to aforementioned DNA damage with subsequent cytotoxic edema. Radiation necrosis is predominately a white matter process that may occur by one or more of the following mechanisms: glial dysfunction, vasculopathy, or immunologic response. Glial dysfunction is supported by histologic changes including white matter necrosis, cystic cavitation with gliosis, and patchy demyelination suspected to be the result of oligodendrocytes injury. Alternatively, vascular injury has been observed histologically as perivascular lymphocytic infiltration, endothelial proliferation, fibrinoid degeneration, capillary occlusion, and intraluminal thrombosis of medium- and small-sized arteries. Endothelial cell injury then causes vasogenic edema. A *mineralizing microangiopathy* is seen in nearly 20% of patients at autopsy and can be appreciated clinically as calcifications at the gray-white junction

on head CT (see Fig. 134.4). Lastly, an *immunologic mechanism* is suspected to occur when irradiated glial cells release antigens that induce an autoimmune reaction. These mechanisms are all triggered by chronic oxidative stress linked to free radical generation and further contribute to advanced atherosclerosis and neurocognitive decline. White matter necrosis is seen after higher radiation doses, whereas lower doses are observed to cause vascular damage, with a more delayed presentation. Asymptomatic animals are found to have a spongy vacuolation of the spinal cord white matter. In contrast, the animals with paralysis were found to have tissue destruction and vascular changes, predominately in the posterior and lateral columns. Long-term vascular damage can lead to advanced cerebrovascular disease. Endothelial damage, subintimal fibrosis and hypertrophy, dysfunction of the elastic membrane, and thickening and fibrosis of the muscular wall all play a role in the advanced vascular disease seen in this population.

Plexopathies and neuropathies can be the result of an occlusion of an artery (eg, subclavian artery stenosis causing a brachial plexopathy) or radiation fibrosis, producing external compression around the nerve. Peripheral nerve ischemia due to radiation injury to the vasa nervorum is also suspected. Autopsies of those with radiation vasculopathy reveal myointimal proliferation, hyalinization, and occlusion.

DIAGNOSIS

The diagnosis for many of the clinical sequela of radiation therapy rests on the identification of their clinical features, time frame between radiation exposure and onset of symptoms, and exclusion of other conditions or inflictions that can produce the same symptoms. Most clinical complications can be classified as *early*, *early-delayed*, or *late* injury, and often a given complication can have different presentations at each stage depending on the dose delivered. The early onset of cerebral edema after radiotherapy can be appreciated on head CT and brain magnetic resonance imaging (MRI) (T2 or fluid-attenuated inversion recovery [FLAIR]), but the clinical diagnosis is often assumed if there is improvement in symptoms after the administration of corticosteroids. Early-delayed leukoencephalopathy is suspected by history of radiation therapy and the time between radiation exposure and symptom onset. T2 and FLAIR sequences on MRI may demonstrate hyperintensities, but these are not specific for the condition. Confidence in the diagnosis of early-delayed leukoencephalopathy is strengthened by the gradual improvement in symptoms without treatment or intervention. Radiation plexopathy due to fibrosis is favored with electromyography demonstrating myokymia. CT and MRI changes consistent with fibrosis increase the likelihood of a causational link but are not conclusive. Endocrinopathies and pituitary dysfunction are diagnosed as described elsewhere in this text. Cognitive and neurobehavioral disturbances are detected through neuropsychiatric assessment. The clinical and imaging features of the various complications of radiation injury are summarized in Table 134.3.

Acute Radiation Sickness

Acutely radiated victims of an occupational or environmental event or accident typically do not know the dose of radiation they were exposed to. Symptoms of acute radiation sickness (ARS) on presentation include nausea, vomiting, diarrhea, or headache. Alopecia and scalp erythema may also be seen. Injury to the pharyngeal mucosa may cause pharyngitis and eustachian tube dysfunction leading to otitis media. The onset, persistence, and severity of symptoms are used to gage the dose and therefore the prognosis of the victim. If neurologic symptoms are present acutely and are not the result of an injury sustained from a blast or other traumatic force, such as a decreased level of consciousness, ataxia, and seizures, the estimated radiation exposure is greater than 10 Gy and mortality is 100%. Those with a moderate radiation dose (2-6 Gy) may develop some mild transient cognitive impairment. Those with a higher dose (~6-10 Gy) will have more significant disturbances in cognition and consciousness that persist beyond 24 hours and have an expected survival of less than 5%. If the radiation dose remains uncertain due to confounders or an ambivalent presentation, the absolute lymphocyte count at 48 hours can provide further insight into the estimated radiation dose absorbed (Table134.4).

Cerebral Edema and Early Delayed Leukoencephalopathy

Symptoms of cerebral edema from radiation injury following therapeutic radiotherapy with high daily dose fractions appear within a few days to weeks and include headache, nausea, and vomiting. Local edema may cause transient worsening of prior neurologic deficits, which can mimic progression of disease (so called "pseudo-progression"). A delayed leukoencephalopathy can present 4 to 10 weeks after radiation with somnolence and headache. This is the result of blood-brain barrier breakdown and defects in the formation and maintenance of the myelin sheath. It is generally self-limited and reversible, although in the long term, advanced small vessel disease may lead to a more permanent leukoencephalopathy. A posterior fossa syndrome of ataxia, dysarthria, and nystagmus may follow radiation to the middle ear area for glomus jugulare tumors.

The early onset of cerebral edema after radiotherapy can be appreciated on head CT and MRI. The latter often demonstrates T2 or T2 FLAIR signal hyperintensity. Ultimately, the diagnosis is clinical and often assumed if there is improvement in symptoms after the administration of corticosteroids.

Radiation Necrosis

Radiation necrosis can also be classified as early, early-delayed, or late-onset but is most often a later consequence of radiation that presents between 6 months and 7.5 years after radiotherapy with clinical manifestations that may mimic the original tumor. Other presentations may include seizures, headaches, or increased intracranial pressure. Focal or lateralizing neurologic deficits can be neuroanatomically linked to the site of the treated malignancy or distant from it. Eighty-five percent of radiation necrosis cases occur within 2 years of treatment. It is more likely to occur with high doses of radiation or reirradiation of previously treated areas.

Radiation necrosis should be suspected when symptoms begin more than 6 months after radiotherapy. Neuroradiologic abnormalities range from focal mass lesions to diffuse white matter changes (Fig. 134.1). Mass lesions are typically at the site of the original tumor/malignancy or in the path of delivered radiotherapy. CT and/or MRI may demonstrate ringlike or heterogeneous enhancement mimicking the original neoplasm.

TABLE 134.3 Clinical Manifestations of Radiation Injury: Features and Risk Factors

Clinical Manifestation	Clinical Features	Imaging Features	Dose[a]	Time Frame[a]	Risk Factors
Acute radiation sickness	Nausea, vomiting, diarrhea, headache	Acute cerebral edema, loss of gray-white differentiation	>2 Gy	Minutes to hours after exposure	Environmental exposure
Nonspecific constitutional symptoms	Fatigue, headache, anorexia	None	Any	Days to weeks after exposure	Extremes of age, comorbid hypertension, and/or diabetes
Acute cerebral edema	Pseudoprogression, encephalopathy	Vasogenic and cerebral edema	>2 Gy	Days to weeks after exposure	Concurrent temozolomide or CTLA-4 agent use
Leukoencephalopathy/ neurocognitive changes	Cognitive slowing	Advanced white matter T2 signal change	>20 Gy, more common after >60 Gy	>1-6 mo after exposure	Extremes of age, comorbid hypertension, and/or diabetes
Radiation necrosis	New or worsening focal deficits	Contrast enhancement, cytotoxic cerebral edema	>50 Gy, higher risk if delivered over shorter time/fewer fractions	6 mo to 7.5 y after exposure	High doses of radiation delivered over fewer fractions
SMART syndrome	Stroke syndrome with associated headache	Heterogenous gyriform enhancement and increased perfusion	>50 Gy	15+ y	Comorbid hypertension and/or diabetes
Myelopathy	Lower extremity paresthesia, weakness, bowel/bladder dysfunction	White matter T2 signal change	>60 Gy, higher risk if delivered over shorter time	1-3 y after exposure	Younger age, high dose, wider field of radiation
Plexopathy/neuropathy	Unilimb paresthesias, pain, or weakness, myokymia on EMG	Swelling of plexus	>60 Gy	3-6 mo	High doses, overlapping fields, axillary focus of treatment, concurrent chemotherapy
Neuroendocrine effects	Growth hormone deficiency, hypogonadism, adrenal insufficiency, and/or hypothyroidism	Leukoencephalopathy, diffuse cerebral microbleeds, vacuolation of cortex and white matter	GH deficiency: >10 Gy Gonadotropin deficiency: >20 Gy Hypothyroidism: >40 Gy Adrenal failure: >45 Gy	>1 y	More common in children
Vasculopathy	Acute stroke syndromes	Advanced large vessel disease, leukoencephalopathy, or mineralizing microangiopathy	>40 Gy	10+ y	HTN, DM
Secondary tumor formation	Symptoms consistent with new/progressive mass lesion	Mass lesion on CT or MRI	>8.5 Gy	Dose-dependent, generally 10+ y	Genetic predisposition, high dose

Abbreviations: CT, computed tomography; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; DM, diabetes mellitus; EMG, electromyography; GH, growth hormone; HTN, hypertension; MRI, magnetic resonance imaging; SMART, stroke-like migraine attacks after radiation therapy.

[a]Doses and time frames listed in this table are those commonly associated with various sequelae, but patients may develop complications at lower doses, especially with increasing time since exposure. Similarly, patients exposed to higher doses of radiation will often develop complications earlier in their course.

TABLE 134.4 Acute Radiation Syndrome Prognosis Based on Acute Symptoms and 48-h Absolute Lymphocyte Count

Radiation Dose (Gy)	Acute Symptoms	24-h CNS Symptoms	48-h Absolute Lymphocyte Count	Prognosis/Mortality
0-0.4	None to very mild, onset ~6 h	None to very mild headache	1,400-3,000 (normal)	Excellent, <5%
0.5-2	None to mild, onset 2-6 h	None to headache	1,000-1,399	Good, <5%
2-4	Mild to moderate, onset 1-2 h	Brief cognitive impairments	500-999	Fair, 5%-50%
4-8	Moderate to severe, onset 10-60 min	Drowsy to confused	100-499	Poor, 50%-100%
>8	Severe, onset within 10 min	Immediate lethargy, coma, seizures	100	Dismal, 100%

Abbreviation: CNS, central nervous system.

FIGURE 134.1 Radiation necrosis on magnetic resonance imaging (MRI). **A:** Coronal T1 post contrast MRI. **B:** Axial T1 post contrast MRI. **C:** Axial T2 FLAIR MRI. An 85-year-old male with history of left trigeminal schwannoma was treated with fractionated stereotactic radiosurgery (3,000 cGy in 5 fractions). Two months after treatment, he presented with worsening trigeminal neuralgia-type pain. The images here demonstrate ring-enhancing lesions with extensive surrounding T2 fluid-attenuated inversion recovery signal change, typical of radiation necrosis.

Angiography and/or perfusion imaging, however, will demonstrate that the lesion is avascular. Initially, changes are typically seen in the white matter but may progress to involve the gray matter over a period of 6 months to 2 years. Diffuse white matter changes are seen as areas of hypodensity on CT or increased signal intensity on T2/FLAIR on MRI (with MRI being more sensitive), do not necessarily correlate with clinical symptoms, and are typically not reversible. Mild or early changes are seen adjacent to the frontal and occipital horns of the lateral ventricles. More extensive or progressive changes extend to include the centrum semiovale. The most advanced show diffuse lesions with a characteristic scalloped configuration. Accompanying changes include cortical atrophy or ventricular dilatation. In all stages, mass effect is rare, and if seen, an alternative process or focal necrosis should be considered.

Distinguishing tumor recurrence from radiation necrosis may be difficult. Both may demonstrate contrast enhancement and diffusion restriction, but recurrent tumor often has lower ADC values than radiation necrosis on diffusion-weighted imaging. Single-photon emission CT and positron emission tomography may be helpful. Hypometabolic areas on positron emission tomography are suggestive of radiation necrosis. Similarly, hyperperfused areas on perfusion magnetic resonance may suggest tumor recurrence over radiation necrosis (cannot be used in the setting of hemorrhage). A reduction in choline levels on magnetic resonance spectroscopy suggests tumor necrosis (and therefore radiation necrosis), whereas an increase could suggest tumor recurrence. Lactate elevations are suggestive (but not diagnostic) of necrosis due to vasculopathy. Serial imaging may be necessary to differentiate between radiation necrosis and disease recurrence or progression. Clinicians should avoid anchoring themselves to a diagnosis based on neuroimaging alone and should have a low threshold for performing a biopsy to increase their diagnostic certainty.

Myelopathy

Radiation-induced myelopathy may also present as an early, early-delayed, or late injury. Early-onset myelopathy is generally seen with ARS and is generally fatal. Early-delayed radiation myelopathy is transient and presents within 6 months of radiotherapy. Lhermitte sign (ie, flexion of the neck causes an electric shock sensation down the spine) is common and was reported in up to 15% of those receiving radiation for Hodgkin lymphoma. Delayed radiation myelopathy presents 1 to 3 years following radiotherapy and presents with painless numbness and paresthesias, which then progress to include a spastic gait, sphincter symptoms, and limb weakness. Less commonly, acute paraplegia occurs acutely over a few hours and in this instance is thought to be the result of vascular injury causing infarction. Also worth mentioning is a syndrome that simulates motor neuron disease, which progress over 1 to 2 years and then plateaus.

Radiation myelopathy is diagnosed via exclusion of other processes and its time of onset in relation to the radiation administration (~1-3 y after radiotherapy). MRI is the preferred diagnostic test and may demonstrate cord swelling, atrophy, or complete subarachnoid block, but it also may be normal. Signal changes on TI (low intensity) or T2 (high intensity) and contrast enhancement may appear 1 month after the onset of clinical symptoms. Beginning about 1 year after onset of symptoms, cord atrophy is seen, and there is no further contrast enhancement. The diagnostic approach should seek to exclude other possible etiologies of the patient's myelopathy, such as extra- or intramedullary tumors, leptomeningeal metastases, or cord compression due to vertebral body abnormalities.

Radiation-Induced Vasculopathy and SMART Syndrome

Radiation-induced vasculopathy typically presents as a transient ischemic attack and/or ischemic stroke. The time course to onset can be short or several decades after radiotherapy. Radiation therapy is an independent risk factor for cerebrovascular disease, particularly after a posttreatment interval of over 10 years. Comorbid hypertension and diabetes mellitus increase the risk of vasculopathy after radiation therapy. Irradiation of the circle of Willis is generally the strongest predictor for stroke, with exponential increase after more than or equal to 40 Gy to these structures; however, there is significant variation in the

FIGURE 134.2 Whole brain radiation. A 45-year-old woman with breast cancer complicated by multiple brain metastases was treated with multiple courses of whole brain radiation. Although asymptomatic, her imaging here demonstrates diffuse leukoencephalopathy with confluence T2 fluid-attenuated inversion recovery hyperintensities **(top three images)** and scattered microbleeds on susceptibility-weighted imaging **(bottom three images)**.

dose-risk association and genetic factors have also been identified as playing a role in the development of vasculopathy after irradiation.

Radiation-induced vasculopathy may present as advanced large-vessel atherosclerotic disease, pronounced small vessel white matter disease, and/or cerebral microbleeds (Fig. 134.2). Moyamoya-like findings have been described as well. The small vessel disease seen on imaging should be distinguished from early-delayed leukoencephalopathy in that it occurs years after irradiation and is irreversible. Radiation vasculopathy is suspected based on history, location and appearance of the lesion(s), and localization to a region of prior radiotherapy. Stenotic lesions from radiation exposure tend to be more longitudinally extensive and are more prone to restenosis after intervention. Small vessel disease may present with a mineralizing microangiopathy with calcifications observable even on noncontrast CT (Fig. 134.3). More commonly, there is increased T2/FLAIR signal in the area of treatment with or without microbleeds seen on susceptibility-weighted imaging. Cerebrovascular malformations have been reported in the field of irradiated tissue as well.

One clinically distinct vascular syndrome is SMART syndrome. This relatively rare condition presents many years after radiation exposure with recurrent complex migraines with focal neurologic findings, typically in patients who have received over 50 Gy of radiation and often to lesions in the posterior fossa. Risk factors include male sex, time since radiation, and genetic susceptibility. It is typically seen in patients treated for childhood malignancies many years after treatment. Deficits are usually transient during an attack; however, recurrent or progressive cases have also been reported, and there is a presumed association with vasculopathy and increased risk for stroke in these patients.

FIGURE 134.3 Mineralizing microangiopathy on noncontrast head computed tomography (CT). **A:** Axial non-contrast head CT set to bone window. **B:** Coronal non-contrast head CT. A 56-year-old male with distant history of childhood lymphoma treated with chemotherapy and radiation underwent magnetic resonance imaging of the brain for new-onset hearing loss. Whereas magnetic resonance imaging showed susceptibility changes initially concerning for hemorrhage, computed tomography shown here revealed diffuse calcifications of the gyri concerning for dystrophic calcinosis. Other than his hearing loss, the patient was asymptomatic from these lesions.

FIGURE 134.4 Stroke-like migraine attacks after radiation therapy (SMART) syndrome on MRI and MR perfusion imaging. **A:** Axial T2 FLAIR MRI. **B:** Coronal T2 FLAIR MRI. **C:** Axial T2 FLAIR MRI. **D:** Axial magnetic resonance perfusion (MRP) image. A 44-year-old male with low-grade oligodendroglioma was treated with resection and stereotactic radiosurgery. Approximately 3 years after treatment, he developed stereotyped episodes of headache; encephalopathy; and left hemibody numbness, hemiplegia, and ataxia with an accompanying left hemianopsia. Magnetic resonance imaging here shows subtle heterogenous gyriform enhancement and with loss of fluid-attenuated inversion recovery suppression and increased flow over this area on magnetic resonance perfusion consistent with stroke-like migraine attacks after radiation therapy syndrome.

Although SMART syndrome is primarily thought to be due to a migraine-like pathology with impaired vascular reactivity and radiation-induced endothelial dysfunction, some studies have suggested a possible epileptic etiology and many described cases have included electrographic seizure as part of the presentation. Thus, electroencephalogram is important to rule out seizure in these patients. Unilateral gyriform enhancement with focal or regional cortical thickening on MRI many years after radiation exposure in a patient with headaches, seizures, and/or focal neurologic findings is suggestive of SMART syndrome (Fig. 134.4). There may be loss of FLAIR suppression and increased flow over this area on perfusion imaging.

Neuropathy and Plexopathy

Radiation plexopathy is observed in three distinct clinical syndromes. A transient plexus injury presents 3 to 6 months following radiotherapy with paresthesias, pain, or weakness. Acute ischemic brachial neuropathy has an acute presentation that does not progress and is painless. Radiation fibrosis presents with painless paresthesias involving the upper (brachial) plexus +/− swelling of the arm about 4 years after radiotherapy. Tumor recurrence can also present in a delayed fashion with paresthesias, but there is typically no swelling, it is painful, and it affects the lower plexus. Electromyography is the diagnostic test of choice and reveals myokymia with the pathognomonic doublets seen on electrodiagnostic testing. Imaging may show increased T2 signal and thickening of the brachial plexus (Fig. 134.5).

Optic Neuropathy and Ocular Neuromyotonia

Similar to peripheral mononeuropathies or plexopathies, patients treated with radiation can develop cranial neuropathies as well. Optic neuropathy presents with painless visual loss, decreased visual acuity, and/ or abnormal visual fields within 3 years of radiotherapy. Exam demonstrates papilledema followed by optic atrophy and hemorrhagic exudates. Imaging may show T2/FLAIR signal hyperintensity such as with other optic neuropathies.

Ocular neuromyotonia presents with tonic spams of extraocular muscles innervated by a particular extraocular nerve that occur during sustained eccentric gaze, resulting in hyperaction of the innervated muscle(s). It most commonly occurs after radiation to the skull base (ie, the oculomotor nerves) and is thought to be due to nerve demyelination and ephaptic transmission versus a possible calcium channel dysfunction.

FIGURE 134.5 Plexopathy. T2 hyperintensity and swelling plexopathy. A 63-year-old female with history of breast cancer treated with local radiation presented to neurology clinic with 11 months of worsening right upper extremity monoplegia, paresthesia, and areflexia. Additional examination revealed right ptosis and miosis (concerning for proximal T1 involvement), and magnetic resonance imaging demonstrated T2 signal hyperintensity and swelling in all three (upper, middle, and lower) trunks of the brachial plexus proximal to the supraclavicular region.

Neuroendocrine Dysfunction

Endocrine dysfunction presents with abnormal growth or puberty in children, with decrease in muscle mass, increase in adipose tissue, infertility, and constitutional symptoms of endocrine dysfunction (fatigue, skin changes, heat/cold intolerance, etc) in adults. This may manifest as a growth hormone deficiency, hypogonadism, adrenal insufficiency, hypothyroidism, and/or hyperprolactinemia. Factors that affect risk in fractionated radiation therapy include total dose, fraction size, age at time of radiation, and length of time after radiation therapy. Growth hormone deficiency is the most common and often only deficiency seen after cranial irradiation, occurring after doses as low as 10 Gy. This is a frequent complication in children undergoing either prophylactic cranial radiation therapy or total body irradiation for bone marrow transplant. Gonadotropin deficiency occurs with doses above 20 Gy and manifests as a failure to enter puberty in children and with amenorrhea, infertility, sexual dysfunction, and decreased libido in adults. Thyrotropin deficiency may occur with doses above 40 Gy, and presentations may include weight gain and lethargy. Adrenocorticotropic hormone deficiency is uncommon, occurring in patients receiving doses over 45 to 50 Gy, and presenting with lethargy, fatigue, fasting hypoglycemia, and hyponatremia. Hyperprolactinemia is featured by delayed puberty, galactorrhea, and amenorrhea in women and decreased libido and impotence in men.

Neurocognitive Effects

Neuropsychological sequela of radiation is most conspicuous when it manifests with a delayed IQ decline, learning disability, or academic failure. These symptoms are seen most commonly in children or adults receiving WBRT, with some studies demonstrating cognitive decline in over 90% of patients in the latter group. So-called "hippocampal sparing" protocols have been shown to significantly reduce the risk and severity of decline LEVEL 1.[1-4] Detailed neuropsychiatric testing can reveal deficits in memory, executive function, processing speed, and verbal selective reminding. MRI will often demonstrate a leukoencephalopathy with diffuse T2 signal hyperintensity as well as scattered microbleeds on susceptibility-weighted imaging (see Fig. 134.3). The incidence and severity of neurocognitive symptoms appears to correlate with the degree of leukoencephalopathy seen on MRI. A normal pressure hydrocephalus-like syndrome of ataxia, cognitive disturbance, and urinary incontinence has been described that may improve transiently with ventriculoperitoneal shunting, although many of these patients go on to develop diffuse cerebral atrophy and dementia despite shunting.

MANAGEMENT

Few nervous system effects from ARS do not have specific therapies. The treatment of ARS is described in other texts and largely includes supportive care and granulocyte-stimulating drugs when significant lymphopenia is seen. Corticosteroids do not have a role in ARS because immunosuppression is one of the most feared and deadly consequences of high-dose ionizing radiation exposures. Treatment is generally supportive and acutely symptomatic patients have a high level of mortality.

In patients who develop constitutional symptoms such as anorexia and fatigue, steroids may be considered, but treatment is generally supportive. In a double-blind trial terminated prematurely, 68 patients with primary or metastatic brain tumors were given methylphenidate versus placebo during radiation therapy with no difference in fatigue or cognition at 8 weeks LEVEL 1.[5,6] Early and early-delayed manifestations of radiation injury in particular are often self-limited and do not require specific treatments. Early cerebral edema, early-delayed leukoencephalopathy, early or early-delayed myelopathy, plexopathies, and neuropathies are often treated with corticosteroids. Among these, only cerebral edema seems to have an appreciable clinical response and in cases of patients with significant cerebral edema before radiation therapy, prophylactic treatment with dexamethasone can be considered. Not uncommonly, there is a transient improvement with corticosteroids in myelopathy, but without alteration of the ultimate course of the disease. Steroids can again be considered in optic neuropathies, and ocular neuromyotonia in particular is treated with carbamazepine or lacosamide.

Similarly, early or early-delayed radiation necrosis is often self-limited and does not require treatment. It is important to distinguish radiation necrosis from disease progression, however, and biopsy or follow-up imaging after 1 to 2 months is generally recommended to exclude the former. In some cases, however, radiation necrosis may cause significant neurologic worsening, cerebral edema, or mass effect, leading to delayed central nervous system injury. In these cases, symptomatic patients are again treated with glucocorticoids as a first line. Refractory cases with ongoing injury from radiation necrosis may be treated with bevacizumab, hyperbaric oxygen therapy, or surgery. There is also limited evidence for use of the free radical scavenger edaravone.

In patients who fail steroids, several randomized controlled trials demonstrated beneficial effect of bevacizumab in reducing brain edema radiologic worsening LEVEL 1.[7,8] Bevacizumab is humanized monoclonal antibody against vascular endothelial growth factor, which inhibits its binding to specific surface receptors on endothelial cells to attenuate blood-brain barrier permeability. Hyperbaric oxygen serves to increase oxygen concentration in ischemic areas of radiation injury and has been shown in several case reports and smaller series to be beneficial patients with radiation necrosis. One study of prophylactic hyperbaric oxygen therapy after SRS for metastases demonstrated decreased rates of white matter injury without known benefit. Randomized controlled trials are needed to further evaluate the role of this therapy in the treatment of radiation necrosis. In rare cases, debulking surgery may be necessary to alleviate mass effect should more conservative measures fail. There is limited evidence that laser interstitial thermal therapy may provide improved outcomes over more traditional surgical techniques in these patients. Finally, one open-label randomized controlled trial demonstrated improvement in both symptoms and MRI findings after treatment with the free radical scavenger edaravone in conjunction with steroids; however, further study of this agent is needed LEVEL 1.[9] Unlike acute and early-delayed reactions, which are usually reversible, later manifestations are generally less responsive to treatment with a more malignant course. There are no known effective treatments for late-onset radiation myelopathy; although treatment with bevacizumab has shown promise in case studies, no definitive evidence exists for its use at this time. Treatments for plexopathy include the prevention of shoulder subluxation, treating lymphedema, and providing analgesia.

Vasculopathy due to radiation injury is treated similar to other nonradiation-related cerebrovascular disease. Large artery vasculopathy has been treated successfully with stenting and

some radiation oncologists recommend yearly carotid duplex screening for large vessel atherosclerosis 2 to 5 years after radiation to the neck. It is reasonable to consider antiplatelet agents for small vessel disease. Although concomitant treatment with hyperbaric oxygen during radiation treatment has been shown to reduce the incidence of white matter injury on imaging, this is of unknown clinical significance and is not regularly employed.

The SMART syndrome does not have any proven or specific treatments; patients often receive a course of corticosteroids and antiepileptics. Some authors advocate for antiplatelet agents and/or statins. It is again important to recognize seizures in this population, and all patients with suspected SMART syndrome should undergo evaluation with electroencephalogram.

Patients with suspected neuroendocrine dysfunction after radiation should have screening labs for hypothalamic and/or pituitary dysfunction and be referred to an endocrinologist. Most will require long-term endocrinology follow-up and hormone replacement therapy.

With regard to neurocognitive symptoms, the best treatment is preventative, and significant clinical evidence exists demonstrating that SRS or hippocampal sparing WBRT offers improved cognitive outcomes compared to conventional WBRT protocols LEVEL 1.[1-4] In patients who do develop symptoms, conflicting data exists on the use of neurostimulants in this population, with one randomized controlled trial showing modest benefit but two demonstrating no effect LEVEL 1.[10] The prophylactic use of acetylcholinesterase inhibitors (and in particular memantine) during radiation treatment in this population is more promising, with randomized controlled trails showing benefit in cognitive performance compared to baseline LEVEL 1.[11,12] Its use has also been linked to significant decreases in brain edema, brain infarct size, and brain vasculature changes following WBRT. A phase II study in 2004 of vitamin E provided some benefit as well; however, the study was not randomized or blinded with a small sample size and no long-term follow-up.

OUTCOME

Prognosis after radiation injury varies widely depending on the complication, timing, and degree of injury. Outcomes after acute radiation syndromes are displayed in **Table 134.2**. For patients treated with therapeutic radiation, acute side effects tend to be more benign in their course and often respond to treatment with steroids. Early cerebral edema, early delayed leukoencephalopathy/demyelination, and ocular myotonia, for example, are nearly always self-limited and reversible. In contrast, more delayed complications tend to be irreversible and are less responsive to treatment. Although acute radiation necrosis is often self-limited and/or easily treated with steroids, more delayed or aggressive cases can be progressive and fatal both with and without treatment. Symptoms of radiation myelopathy are also not expected to improve. Outcomes after vasculopathy are related to the efficacy and timing of revascularization efforts. Outcomes after SMART syndrome have only been described in case series, but up to 50% appear to have residual neurologic deficits and these patients may be at increased risk for stroke. Radiation plexopathy, neuropathy, and optic neuropathy are usually irreversible. Neuroendocrine effects are permanent in most cases, requiring lifelong hormone replacement therapy. Cognitive deficits are typically not reversible and not uncommonly progressive, resulting in death or permanent disability and dependence.

Electrical and Lightning Injury 135

Imad Khan and Christopher Zammit

KEY POINTS

1. Electrical injuries can be differentiated into low- and high-voltage electrical injuries (LVEI, HVEI).
2. LVEI severity, such as electrical wire contact, depends on the amount of current and whether current is alternating or direct.
3. High voltage electrical injuries, such as lightning strikes, lead to violent muscle contractions and burn injuries at the point of contact and along tissues of low resistance such as nerves, muscle and blood vessels.
4. Long term neurological symptoms after electrical injury may include neuropsychiatric dysfunction, Parkinsonism, progressive motor deficits, myelopathy, focal dystonia, and tics.

INTRODUCTION

Electrical injuries (EI) and lightning strikes (LS) have been reported to cause a variety of neurologic injuries. Interestingly, although some of the associated neurologic sequelae are seen acutely, others develop in a delayed fashion. Although both EI and LS produce injury via the creation of an electrical current, the neurologic complications of each can be quite different.

Low-voltage electrical injuries (LVEI) are defined as resulting from exposures of less than 1,000 V, whereas greater exposures are termed *high-voltage electrical injuries* (HVEI). They are to be further distinguished as being the result of a direct current or an alternating current (AC), with the latter producing approximately 3 times as much injury as the former. The LS are exceptionally brief, with voltages on the order of the millions, and produce a unique constellation of immediate and delayed injuries.

EPIDEMIOLOGY

The first death in the United States related to an artificial electrical source occurred in front of a crowd in Buffalo, New York, in 1881 when an intoxicated man came into contact with a generator. His death was seen as being quite painless, leading to the use of electrocution as a humane method of capital punishment. Formal reporting of electrical and lightning injuries is not required, limiting the accuracy of existing epidemiologic data.

There are an estimated 3,000 EI per year in the United States, including 1,000 deaths. Children are more likely to suffer LVEI, whereas adolescents and adults more commonly experience HVEI, which are frequently occupationally related.

Over 15,000 police departments across the United States use conducted energy weapons (CEWs), such as stun guns and TASER devices to restrain suspects. Cardiac arrests have occurred after the uses of CEW, but a causational link has been proposed in only a minority of cases. In the majority of circumstances, excited delirium and/or intoxicants ingested by the victim are blamed for causing the arrest.

Three hundred to 1,000 lightning injuries occur per year in the United States, with an estimated mortality rate of 10%. Many victims either do not seek care at the time of the injury, and half of the immediate deaths are transported directly to the coroner and never reported. Victims are usually men (4.5:1 male-to-female ratio) in their second to third decade of life and are performing outdoor recreational or occupational activities.

PATHOBIOLOGY

Electrical Injuries

The severity of LVEI is subject to the pathway of the current and proportional to the duration of exposure and amount of current (milliamperes). Low-voltage AC, in contrast to low-voltage direct current, can produce continuous involuntary muscle contractions. If the victim grips an AC electrical source with their hand, tetany of the flexors of the upper extremity prove stronger than the extensors, causing the victim's grasp of the source to be strengthened. Currents of 6 to 9 mA or greater, which can be achieved via exposure to a standard 110-V household outlet, exceed the "let-go threshold," rendering the victim incapable of dissociating himself or herself from the source. If the current flows through the thorax, tetany of the muscles of respiration can occur, causing the victim to suffocate. Currents of approximately 50 to 100 mA can cause ventricular fibrillation; the current threshold is inversely proportional to the duration of exposure.

Direct contact with a high-voltage electrical source more commonly produces diffuse, sudden, and violent muscle contractions that thrust the victim away from the source, causing traumatic insults in addition to the EI. Even with brief exposures, the high voltages convey a tremendous amount of energy, which is released via electrothermal heating at points of high resistance (eg, the skin, where full-thickness burns are seen). Internally, the current is carried along tissues of low resistance, such as the nerves, muscles, and blood vessels. Immediate effects include muscle necrosis and small-vessel thrombosis, resulting in threats to extremity viability and peripheral nerve integrity through compartment syndromes and limb ischemia.

In contrast to a direct-contact injury, a spark can jump from a highly charged source to a ground source, forming an electrical arc, where temperatures can reach 2,500°C. When a victim is caught in the path of the arc, he or she suffers cutaneous thermal burns and blast injuries when the suddenly heated air rapidly cools, in addition to a HVEI by becoming part of the conduction pathway of the current.

The CEWs are reported to be high voltage (with an initial charge of ~50,000 V). However, the victim does not experience this voltage. Instead, it allows for an arc to be created if the

barbs do not make contact with the skin, which happens about 30% of the time. Once contact is made, the voltage immediately decreases to provide a current of approximately 2 mA in brief pulses at a rate of 20 times per second, producing involuntary muscle clonus (much like an AC circuit), preventing the suspect from resisting. Because of the low current, EI is rare with CEWs, and most injuries, when they do occur, are traumatic and related to when the victim falls to the ground.

Lightning Strikes

Lightning victims can be directly struck with the discharge, receive current via an adjacent object that was directly struck (side flash), become part of the ground current when their feet are apart (step voltage), be the conduit for currents that originate from the ground and discharge toward the clouds (upward stream), and/or experience a concussive or blast injury from the rapid heating and cooling of the air (thunder). Curiously, some of the injuries typically seen with direct-contact HVEI are not found in lightning injuries, and entry and exit wounds are only seen in a minority of cases, suggesting that most, if not all, of the current flows external to the victim. This is thought to result in a powerful magnetic field being created over the victim, causing electrical currents to flow internally through low-resistance tissues (ie, nerves, muscles, blood vessels), resulting in powerful muscle contractions and medullary dysfunction leading to apnea, asystole, and a tremendous catecholamine surge.

Ball lightning is a poorly understood, spherical, mobile electrical field observed floating along power lines, down aisles of airplanes, or through the air during lightning storms. Coronal discharges are another form of lightning-related phenomenon thought to be caused by air breakdown when electric stress at a conductor's surface exceeds a certain value, causing a colored glow near the surface of the conductor. Neurologic sequelae have been reported in those that have come into contact with ball lightning and coronal discharges, including peripheral neuropathy, ataxia, and cognitive and memory deficits.

The pathophysiology of neuronal injury after EI and LS is not clear, and several plausible mechanisms have been reported. The low resistance of nerves makes them a conduit for the electrical current, causing tremendous excitatory discharges, which result in microglia activation, electroporation, and chromatolysis. Electroporation is the destabilization of neuronal cell membranes from electrical current–induced changes in cellular proteins, resulting in their dysfunction and perhaps ultimate death. Microglia activation produces an inflammatory response suspected to result in injury to neurons and oligodendrocytes. Upregulation of postsynaptic cortical γ-aminobutyric acid B receptors is also a suggested consequence of the excitatory impulse based on the results of experiments using transcranial magnetic stimulation in patients with HVEI. Axonal injury and demyelination have been observed in EI and LS victims on magnetic resonance imaging, nerve conduction studies, and autopsy.

Blood vessels similarly conduct electrical current, which has been observed to cause microvascular thrombosis and large vessel vasospasm, with some case reports of cerebral thrombosis. Endothelial cell dysfunction at the capillary level resulting in tissue ischemia is a proposed etiology for some of the delayed clinical consequences.

Muscles are also low resistance and therefore conduct a great deal of electrical current. Sarcolemmal injury is a proposed cause of the protracted fatigue reported by many victims of HVEI.

CLINICAL FEATURES

The immediately clinical presentation of EI and LS can range from a minor contact burn to cardiac arrest. In EI due to direct contact, particularly HVEI, there are often significant cutaneous burns with much more extensive internal burn injuries, particularly involving muscles, small vessels, and tendons. Limb amputation may be required, and rhabdomyolysis is frequent in HVEI. Traumatic injuries to the head and spinal cord are also common. Vasospasm and cerebral arterial thrombosis, both immediate and delayed, have been reported. Myelopathy is frequently reported and occurs at a spinal level consistent with the path of the electrical current. Contact injuries to the head and LS may cause a multiple-level myelopathy when the current exits through the foot. Myelopathy may occur in a delayed presentation, with a time period that is inversely proportional to the patient's age. Curiously, peripheral neuropathy is not commonly seen, but when it does occur, it tends to affect motor nerves more than sensory and recently has been described to be axonal.

Neuropsychiatric symptoms, cognitive and memory impairment, autonomic dysfunction, fatigue, chronic headaches, and sleep disturbances are quite common among survivors. The constellation of symptoms is similar to those seen after a traumatic brain injury.

Cherington has divided the neurologic complications of lightning injury into four categories. Category I are temporary and benign, category II are prolonged and permanent, category III includes delayed symptoms, and category IV are traumatic neurologic injuries that occur secondary to falls, sudden violent muscle contractions, or blast effects. **Table 135.1** summarizes these injuries.

Keraunoparalysis, or Charcot paralysis, is an immediate, transient paralysis seen in some LS victims. It involves the lower extremities more than the upper and is characterized by pale limbs with diminished or absent pulses, sensory symptoms, and hypertension. Strength and sensation typically improve to baseline within hours, sometimes sooner. A catecholamine surge has been suspected, but not proven, to be the cause.

Cerebellar dysfunction, including stroke and cerebellar ataxia, is a rarely reported complication of LS described in a few case reports. In the case of cerebellar stroke, posterior fossa edema can ensue, putting the patient at risk of brainstem compression.

Several case reports have attempted to suggest a link between EI/LS and amyotrophic lateral sclerosis; however, several recent reviews have summarized the available data and reports and concluded that any link is quite unlikely.

TABLE 135.1 Neurologic Complication in Victims of Lightning Strikes

Category I	Headache, numbness, weakness, depressed level of consciousness, keraunoparalysis (Charcot paralysis)
Category II	Hypoxic encephalopathy; cognitive deficits; memory and attention impairment; mood, behavioral, and sleep disturbances; fatigue; autonomic dysfunction; cold insensitivity; acute ischemic stroke; intracerebral hemorrhage (basal ganglia or brainstem); myelopathy
Category III	Parkinsonism, progressive motor disease, focal dystonia, and tics
Category IV	Traumatic intracranial hemorrhage, spinal cord injury due to fractures, or hemorrhages

DIAGNOSIS

Victims of EI or LS with an altered level of consciousness, focal deficit, or paralysis on presentation should have emergent diagnostic imaging of the head and/or spine performed to evaluate for traumatic injuries or acute ischemia, which may warrant prompt interventions. Acute cerebral ischemia many be secondary to thrombosis or vasospasm; emergent computed tomography or conventional angiography should be considered.

MANAGEMENT

Specific treatments for the neurologic sequela of electrical and lighting injuries have not been described. Intravenous thrombolytics and/or endovascular therapy (clot retrieval if thrombosis or angioplasty/intra-arterial therapy if vasospasm) should be considered in patients presenting with a sudden onset of focal neurologic deficits after an EI or LS. Victims who are resuscitated after a cardiac arrest and not following commands should be considered candidates for targeted temperature management, barring other contraindications. Similarly, if the victim remains comatose for longer than 2 hours without an alternate explanation, it may suggest he or she was transiently asystolic and/or apneic, particularly in the setting of a LS. Cardiac automaticity and ventilation may have spontaneously resumed but not without suffering a hypoxic-ischemic cerebral injury. The astute clinician should consider targeted temperature management in this setting as well because the event is the equivalent of return of spontaneous circulation in a cardiac arrest patient who received an active resuscitation. Traumatic injuries should be treated accordingly. Survivors of EI and LS may be referred to an international support group, Lightning Strike & Electric Shock Survivors International, Inc. (http://www.lightning-strike.org).

OUTCOME

The neuropsychiatric complications, cognitive deficits, and autonomic disturbances seen after EI and LS are most commonly permanent and at times progressive. Myelopathy may improve, and recovery has been seen in some victims, but most are left with persistent symptoms. Cardiopulmonary resuscitation success rates have been higher in victims of electrical and lightning injuries than from other causes even when the interval from injury has been prolonged. Outcomes after EI or LS complicated by a cerebral infarction or hypoxic-ischemic injury are only found in case reports or case series, making accurate estimations impossible.

Decompression Illness 136

Matthew R. Leach and Christopher Zammit

KEY POINTS

1. The diagnosis of decompression illness (DCI) is clinical and characteristic symptoms upon decompression consistent with DCI should be treated as such.
2. Initial treatment for DCI is high fraction oxygen and recompression.
3. Transport to hyperbaric centers should occur at low altitude.
4. Patients with neurologic sequelae from decompression illness should wait at least 4 to 6 weeks before returning to diving.

INTRODUCTION

The symptoms of decompression illness (DCI) have been observed in underwater and caisson workers building underwater pier and bridge pilings since the early 1800s, when it was coined "caisson disease." Today, DCI refers to the sequela that result from arterial gas embolism (AGE) and decompression sickness (DCS). Both conditions are the result of rapid changes in ambient pressure that cause dissolved inert gases to emerge in the circulation as bubbles. The rapid growth in popularity of underwater diving with a self-contained underwater breathing apparatus, particularly by travelers, has made DCS a diagnostic possibility even in land-locked areas. Although this chapter focuses on DCI, other dysbaric conditions with neurologic inflictions or complaints are also briefly discussed, which include middle ear barotrauma (MEBT), inner ear barotrauma (IEBT), alternobaric vertigo (ABV), carbon monoxide poisoning, nitrogen narcosis, oxygen toxicity, and swallow water blackouts.

EPIDEMIOLOGY

DCS has been observed in those who perform submersion activities (eg, SCUBA, saturation, or breath-hold diving), high-altitude aviation (eg, U-2 pilots), and simulated altitude ascents. AGE can occur after resurfacing from depths of only 1 to 1.5 m, whereas DCS is never seen after surfacing from depths of less than 6 m and very rarely occurs after dives less than 10 m in depth. AGE can occur if the diver rapidly ascends to the surface, holds his or her breath during ascent, or has intrinsic lung disease, particularly those with blebs and asthmatics. DCS risk factors include longer submersion times, deeper submersions, high exertion and warm temperatures during the dive, cold temperatures after the dive, older age, obesity, dehydration, and male gender. Divers with a patent foramen ovale (PFO) appear to be at increased risk (odds ratios of 2.6-5.6) for neurologic DCI when compared with divers without a PFO. Dive computers and tables are available to advise whether "decompression stops" are required during ascent to mitigate the DCS risk and have significantly reduced the incidence of DCI and dysbaric conditions over the last several decades.

DCI is estimated to occur in 2 to 10 out of every 10,000 dives, with higher rates in U.S. Navy and commercial divers and the lower rates in recreational divers. The Divers Alert Network, a not-for-profit organization dedicated to improving diving safety for all divers founded at Duke University produces an annual report, which profiles diving-related complications. Statistics from the most recent report are outlined in **Table 136.1**. Although total calls to the Divers Alert Network have been increasing over the last 10 years, the majority of reports deal with barotrauma or environmentalism issues, and fatalities from DCI have been decreasing, possibly due to the advent of the aforementioned dive computers. The number of calls to the Divers Alert Network and fatalities from diving injuries are trended in **Figure 136.1**.

DCS is less commonly seen in high-altitude flying, when compared with submersion activities, and when observed, the symptoms are typically less severe and rarely include neurologic manifestations. A notable recent exception are Air Force U-2 pilots who fly at altitudes of up to 70,000 ft (21,336 m) in suits that are pressurized to approximately 30,000 ft (10,058.4 m) above sea level.

PATHOBIOLOGY

DCI is believed to result from bubbles of inert gas, particularly nitrogen, being formed in the circulation during decompression. The concentration of inert gas in plasma is directly proportional to the ambient pressure. In the case of submersion, the ambient

FIGURE 136.1 Incidence of calls to the Divers Alert Network (DAN) emergency hotline and diving-related fatalities. Data from the DAN annual reports from 1992-2017, available publicly at www.diversalertnetwork.org. Despite a significant increase in calls to the DAN emergency hotline, diving-related fatalities have decreased since the 1990s, likely due to a combination of increased safety awareness and improved technology. Most importantly, the advent of dive computers which can advise divers on a safe speed of ascent has likely contributed to decreased mortality. Serious injuries—tracked only since 2010—have also decreased over the last few years.

pressure is increased, causing inert gases, mostly nitrogen, to become intensely dissolved in the blood and tissues of the body. The amount dissolved also increases as the temperature rises. Upon ascent (whether that is resurfacing from a dive or ascending in elevation, as in aviation), these inert gases become supersaturated and come out of solution. Ideally, the gas is delivered to the alveoli, where it is expired. In reality, gas bubbles can be observed via ultrasound in the blood of all divers upon emergence from a dive. Typically, the pulmonary circulation filters the bubbles and the diver does not experience any symptoms. However, if the quantity of bubbles is too great, they will buildup and occlude small veins and lymphatic vessels. At high bubble loads, the pulmonary vasculature also develops occlusions, increasing right heart pressures and raising the possibility of opening an otherwise closed PFO through which bubbles can pass into the arterial circulation.

In addition to vessel occlusion, intravascular bubbles are known to irritate the endothelium, causing capillary leakage, and platelet, complement, and cytokine activation, leading to third spacing, hemoconcentration, small-vessel thrombosis, and eventually hypotension. The occlusive action in the venules combined with small-vessel thrombosis is hypothesized to be the cause of the cerebral, vestibular, and spinal cord injuries and dysfunction in neurologic DCS. Inert gases preferentially dissolve in tissue with a high lipid content, such as the central nervous system (CNS), where the emergence of nitrogenous bubbles is suspected to contribute to neurologic dysfunction and injury.

AGE has a slightly different pathophysiology. Alveolar gas that abruptly expands on decompression (as per Boyle law) and is not ventilated appropriately will force itself through the alveolar-capillary membrane and directly enter the arterial circulation, where it produces mechanical obstructions. The most notable clinical sequela occurs when the cerebral or coronary vessels are occluded, producing ischemic strokes and myocardial infarctions.

MEBT and IEBT occur during compression when the eustachian tube collapses and the middle ear cannot equalize its pressure with the ambient pressure. In MEBT, the tympanic membrane ruptures, exposing the middle ear to the water, causing vertigo and, at times, a seventh cranial nerve palsy. IEBT is the result of a sudden equalization of pressure in the inner ear, causing injury to the cochleovestibular system. In contrast, ABV occurs during ascent when gases expand in the middle ear but cannot escape to allow equalization.

Nitrogen narcosis is a result of high concentrations of dissolved nitrogen that can occur at depth of greater than 100 ft (30.48 m). CNS oxygen toxicity can occur when the partial pressure of oxygen exceeds 1.4 atm. Compressed air tanks can be contaminated with carbon monoxide or carbon dioxide if the compressor's exhaust is too close to the air intake, causing carbon monoxide poisoning. Symptoms would be expected to occur during decent or at depth, in contrast to DCI that occurs with ascent or after surfacing. Swallow water blackouts occur in divers who hyperventilate ambient air prior to a dive, driving their arterial carbon dioxide levels very low without increasing their arterial oxygen content. During the dive, carbon dioxide levels do not increase sufficiently to increase respiratory drive, whereas oxygen levels fall, causing a loss of consciousness.

TABLE 136.2 Neurologic Manifestations and Treatment of Diving-Related Maladies

Sequelae	Manifestations	Exposure	Timeframe	Treatment	Risk Factors
Decompression sickness type 2	Diverse neurologic symptoms, both focal and nonfocal	Typically dives >10 m in depth	>10 min after surfacing up to 24 h	Hyperbaric O_2 therapy	Longer submersion times, deeper submersions, high exertion and warm temperatures during the dive, cold temperatures after the dive, older age, obesity, dehydration, male gender
Arterial gas embolism	Focal neurologic deficit/acute stroke syndromes	Can occur with relatively brief, shallow dives >1 m	<10 min after surfacing		Breath holding during ascent, intrinsic lung disease
Middle ear barotrauma	Vertigo, hearing loss	Rapid descent	Develops mid-dive	Supportive care	Sinus congestion or ear infection, anatomic abnormalities, smoking, pregnancy
Inner ear barotrauma	Vertigo, hearing loss, ruptured TM, CN VII palsy			ENT consultation and surgical repair	
Nitrogen narcosis	Depressed level of alertness	Prolonged, deep dives		Hyperbaric O_2 therapy	Longer submersion times, deeper submersions, use of traditional oxygen mixtures

Abbreviations: CN, cranial nerve; ENT, ear, nose, and throat; O_2, oxygen; TM, tympanic membrane.

Of note, the use of oxygen-enriched, helium-oxygen, and helium-oxygen-nitrogen mixtures for prolonged and/or deep dives has been shown to decrease the risk of bubble formation, which may decrease the risk of DCS LEVEL 1.[1]

DIAGNOSIS

DCS has been divided into two clinical categories, type 1 (DCS1) and type 2 (DCS2). The majority of the time, DCS presents within 24 hours of decompression, but delayed presentations have been seen, particularly in those that have flown or ascended in altitude shortly after decompression. DCS1 includes signs and symptoms related to the integumentary, lymphatic, or musculoskeletal system. The patient will describe joint aches and pains, itching, or extremity edema, and a lenticular skin rash believed to be due to venous status, known as *cutis marmorata*, can be observed.

DCS2 can include features of DCS1 with additional symptoms related to the CNS, lungs, or vestibular system. The pulmonary symptoms, which include a cough, dyspnea, or chest pain, have been called the chokes. Vestibular symptoms, also known as *the staggers*, manifest as vertigo, nystagmus, nausea, or vomiting and can be difficult to differentiate from ABV because both can occur on ascent. The symptoms of cerebral DCS can include headache, diplopia, dysarthria, paresthesias, weakness, personality changes, disorientation, fatigue, ataxia, drowsiness, and even lethargy. Visual disturbances include optic neuropathy, homonymous hemianopsia, and central retinal artery occlusion. Spinal cord DCS presents with limb weakness, numbness, paresthesias, incontinence, priapism, urinary retention, or back/pelvic pain.

AGE has a dramatic and abrupt presentation, occurring during ascent or within 10 minutes of surfacing, and is commonly found to be the cause of death in diving fatalities. The presentation can include a variety of neurologic changes, including stroke syndromes, and may include pulmonary symptoms in about half of the cases. It can be difficult to distinguish AGE from DCS2 but treatment is the same, and sorting out the diagnosis is of academic interest only.

MEBT, IEBT, and ABV all have similar symptoms. MEBT will often include a ruptured tympanic membrane. IEBT should be distinguished because the symptoms will be persistent and often require referral to an otolaryngologist. IEBT and vestibular DCS may be difficult to distinguish as well. A history of a sudden symptom onset upon equalization of pressures suggests IEBT. Cerebellar infarcts have been seen as a result of DCS and should be treated the same as vestibular DCS (Table 136.2).

The diagnosis of DCS is clinical. Any symptoms upon decompression consistent with DCS should be treated as such. It is important to remember that DCS has been reported up to 24 hours after a dive, although severe neurologic complications usually appear within 10 minutes of surfacing, and 90% of patients present within the first 3 hours. There are sporadic reports of carotid artery dissection and one report of an epidural spinal hematoma in a breath-hold diver, but these cases are the exception, and recompression should not be delayed.

Magnetic resonance imaging (MRI) lesions have been seen in DCI, but they lack sensitivity because even those with incomplete recovery have been observed to have normal serial imaging. AGE findings are similar to those seen with thrombotic emboli (ie, diffusion-weighted imaging hyperintense with low ADC values acutely). Magnetic resonance findings in DCS2 include both foci of ischemia as well as T2 hyperintense lesions without diffusion restriction. The latter demonstrate a preponderance for white matter, possibly due to the high fat content of myelin and high solubility of nitrogen in fat, although lesions are commonly seen in grey matter as well. Similarly, in spinal DCI, there is predominant involvement of thoracic cord segments due to again high fat content as well as relative hypoperfusion leading to poor nitrogen "washout" during ascent. Many of these T2 signal changes seem to be reversible with timely recompression, although there is often discrepancy between clinical and radiographic outcomes and imaging findings should not influence acute treatment decision making. Divers without a history of neurologic DCS have rarely been reported to have abnormal MRIs, but there are only a handful of controlled studies to fully describe the specificity of neuroimaging. Spinal canal stenosis has been associated with the occurrence of spinal DCS and MRI lesions, but it is not associated with clinical outcomes.

MANAGEMENT

DCI is a medical emergency that calls for the immediately administration of 100% oxygen and recompression. Large-scale observational evidence suggests that timely recompression optimizes outcomes and hastens recovery. More recent publications challenge whether time to recompression impacts the rates of recovery in those with neurologic DCS, but the datasets are small and limited to observations. Therefore, expeditious recompression remains the standard of care, and DCS must be considered a medical emergency.

Hyperbaric oxygen therapy (HBT or HBOT) can be provided in monoplace or multiplace chambers, with the later allowing for hands-on treatment of the patient, if needed. HBT promotes the dissolution and elimination of gasses from tissues, increases delivery of oxygen to ischemic tissues, reduces tissue edema and blood vessel permeability, counteracts the adherence of leukocytes to brain vessels, and partially blocks lipid peroxidation in reperfused tissues. HBT recommendations for DCS and AGE can be found in the U.S. Navy Diving Manual (see "Suggested Readings"). Serial HBT dives are performed until benefit is not seen with consecutive treatments. All patients being considered for HBT should have a chest x-ray for evaluation of pneumothorax and pneumomediastium because untreated pneumothorax is a contraindication for recompression and air transport. Patients requiring air transport to HBT should be flown at the lowest safe altitude (recent recommendations are <500 ft [152.4 m] above surface level) or in a pressurized aircraft. Portable chambers that allow for partial recompression are available. For chamber locations and emergency information, U.S. physicians should contact the Divers Alert Network, at 1-919-684-9111, a 24-hour hotline. In cases where safe, timely transport to HBT is not available, in-water repressurization is a reasonable alternative, although more data is needed to determine the exact protocol for this approach LEVEL 7.[2,3]

Otherwise, treatment of DCI is supportive. Patients should be maintained normothermic because warmer temperatures hasten the absorption of dissolved inert gasses, but hyperthermia may worsen neurologic injury. Isotonic, non–dextrose-containing intravenous fluids should be administered because many of these patients are hemoconcentrated. If AGE is suspected, intravenous lidocaine is commonly provided because randomized evidence from the cardiac surgery literature, where AGE and cerebral injury are commonly seen, suggests it has neuroprotective benefits. Aspirin is considered by many, without evidence to support its use. A randomized controlled trial of tenoxicam for DCS demonstrated that it hastened recovery and reduce the number of required recompressions from 3 to 2, but clinical outcomes were no different LEVEL 7.[4] Preliminary evidence is promising for perfluorocarbons, but clinical trials are needed. A small study from the 1990s suggested that a helium-oxygen mixture might be superior to an air-oxygen mixture during recompression, but the results have not been reproduced. A recent study of PFO closure in divers suggests it reduces the incidence of DCS and the quantity of ischemic brain lesions on MRI.

OUTCOME

Cerebral DCS outcomes are similar to ischemic stroke survivors, as one series found, the National Institutes of Health Stroke Scale, to have a similar ability to predict outcomes in both conditions. Spine DCS outcomes have been found to be worse in those older than 42 years of age, with bladder symptoms, with progressive symptoms upon decompression, with initial severe symptoms, and with MRI abnormalities. One-quarter to one-third of spinal cord DCS victims will make an incomplete recovery. Although there is no data to support specific return-to-diving guidelines for recreational divers, the U.S. Navy handbook permits divers with DCS1 symptoms, which resolved on initial treatment to return to diving after 7 days, and those with DCS2 symptoms, which resolved on initial treatment to return to diving after 30 days. The Divers Alert Network recommends that patient with DCS2 symptoms wait at least 4 to 6 weeks before diving and that symptoms requiring serial treatments warrant 4 to 6 months abstinence from diving and neurologic reevaluation. Vestibular symptoms should be given extra caution and also merit 4 to 6 months delay with thorough evaluation for an intact vestibular system before return to diving. Further caution should be taken in patients with multiple medical comorbidities in all cases.

Arthur M. Mandel

KEY POINTS

1. Premature infants are vulnerable to intraventricular hemorrhage due to the fragile vasculature in the germinal matrix. Prognosis varies, depending on the hemorrhage grade.
2. Hypoxic-ischemic encephalopathy is a major cause of morbidity in neonates, but therapeutic hypothermia is an effective treatment.
3. Seizures are more common in the newborn period because of a predisposition to neuronal excitability. There is a broad etiology, which helps determine treatment.
4. Stroke in neonates are ischemic, hemorrhagic, or due to sinus venous thrombosis. Treatment and outcome depends on cause, extent, and location of the injury.
5. Periventricular leukomalacia typically is seen in premature infants and can result in spasticity, cognitive, or visual complications.

Pediatric neurologists treat many children with brain injuries that originate in the perinatal period and cause mental retardation, cerebral palsy, and/or seizures. This chapter focuses on some of the most common disease processes affecting neonates.

GERMINAL MATRIX-INTRAVENTRICULAR HEMORRHAGE

Epidemiology

Low birth weight and prematurity increase the risk of germinal matrix hemorrhage (GMH) and intraventricular hemorrhage (IVH), and the incidence and severity of IVH increases with earlier prematurity and lower birth weight. The prevalence of periventricular IVH in newborns weighing less than 1,500 g has declined, falling from approximately 40% in 1980 to 20% since the late 1990s. Corticosteroid therapy prenatally and surfactant use after birth have contributed to the decline of IVH. However, with the increased survival rate of extremely low birth weight infants, there are more infants at highest risk, with a risk of 45% in infants less than 1,000 g. In a population-based study in Switzerland, IVH rates decreased 3.5% with each added week of gestation.

Severe IVH (defined as Papile grades III-IV, see in the following text) increases with decreasing gestational age. In a large, multicenter registry of infants of very low gestational age (22-28 wk) and birth weight (401-1,500 g), born between 2003 and 2007 in the United States, 16% overall had severe IVH, and the prevalence increased with decreasing gestational age, from 38% at 22 weeks to 7% at 28 weeks.

Antenatal glucocorticoid therapy decreases the risk of GMH-IVH. A GMH-IVH is more likely to develop in infants requiring neonatal transport. Increased risk of GMH-IVH also is associated with respiratory distress (presumably affecting cerebral blood flow and central venous pressure), rapid increases in arterial blood pressure as well as hypotension, and cardiopulmonary resuscitation.

Pathobiology

The germinal matrix is a well-vascularized and highly cellular layer between the caudate nucleus and thalamus, which gradually involutes during the fetal period. It is susceptible to hemorrhage because of the friable nature of its capillary network. The risk for hemorrhage is further exacerbated by disturbances in cerebral blood flow, through either hypotension or lower cerebral perfusion, possibly lowered further by positive pressure ventilation through endotracheal intubation, and/or through hypoperfusion-reperfusion coupled with immaturity of intrinsic cerebral vasoreactivity and autoregulatory mechanisms. Other factors potentially increasing risk of IVH during prematurity are metabolic (hypoglycemia, hypernatremia), hematologic (anemia, thrombocytopenia), and immunologic (chorioamnionitis, immaturity of antioxidant responses or other immune responses).

The Papile grading system, with some modification, is the most commonly used scale to describe the severity of the IVH (Fig. 137.1). The IVH may remain in the matrix area (grade I), or rupture into the lateral ventricles (grade II), which can result in ventricular enlargement or distension (grade III). Grade IV, now termed *periventricular hemorrhagic infarction* (PVHI), refers to extensive IVH with parenchymal involvement, likely due to terminal venous occlusion, venous infarction, and subsequent secondary hemorrhage.

Late in the course after IVH (1-3 wk after the initial hemorrhage), especially with more severe IVH, there can be posthemorrhagic hydrocephalus, or progressive ventricular dilatation, thought to result from impaired reabsorption of cerebrospinal fluid (CSF) because of inflammation of the subarachnoid villi. Usually, impaired reabsorption results in a communicating hydrocephalus, although there can also be a noncommunicating hydrocephalus due to localized obstruction or scarring.

Clinical Manifestations

Most IVH in premature infants occurs within the first 5 postnatal days, with the majority occurring on the first day of life. Late IVH is associated with low cerebral blood flow, usually from systemic processes.

FIGURE 137.1 Papile grading system for neonatal intraventricular hemorrhage, shown by head ultrasonography. Echodensities are seen in periventricular region (A, grade I), with rupture into the lateral ventricles (B, grade II), and with ventricular enlargement (C, grade III). Periventricular hemorrhagic infarction (D, grade IV) has parenchymal involvement. (From El-Dib M, Massaro AN, Bulas D, Aly H. Neuroimaging and neurodevelopmental outcome of premature infants. *Am J Perinatol*. 2010;27[10]:803-818.)

The clinical presentation of IVH varies, depending on severity. Grade I IVH is usually asymptomatic. Many grade II and some grade III hemorrhages are clinically silent, but there may be a saltatory course evolving over hours to days, characterized by nonspecific findings of altered level of consciousness, hypotonia, eye movement changes, subtle changes in movement, decreased spontaneous movements, and disturbed respiratory function. Some grade III hemorrhages produce hydrocephalic symptoms of varying severity, and if seen in combination with PVHI, there may be signs of severe apnea, bradycardia, extensor posturing, and opisthotonus. There also may be flaccid weakness, cranial nerve abnormalities including fixed pupils to light, most likely leading to unresponsiveness and death within hours. There may be clonic limb movements, which some clinicians have labeled as seizures, although there is usually little electroencephalography (EEG) correlation. Most infants who die have other lesions, such as periventricular leukomalacia (PVL) (see section on "Periventricular Leukomalacia"), brainstem necrosis, or cerebellar necrosis.

Diagnosis

Cranial ultrasonography is the preferred imaging modality because of its portability, its ability to delineate blood in the

parenchyma and ventricles as well as ventricular size, and its lack of ionizing radiation. Routine ultrasound screening should be performed in all infants with a gestational age younger than 30 weeks, at age 7 to 14 days, and then repeated at 36 to 40 weeks gestational age. Ultrasonography should be strongly considered in infants with abnormal clinical signs such as changes in neurologic or respiratory status or with systemic conditions, which can predispose to IVH.

Computed tomography (CT) or magnetic resonance imaging (MRI) have limited usefulness as routine screening tools, because of their lack of portability, exposure to ionizing radiation (CT), and a longer examination time (MRI). However, these modalities may be helpful in documenting other lesions, such as parenchymal abnormalities or subdural or posterior fossa hemorrhages. It is best to avoid CT scanning because of the exposure to ionizing radiation, if MRI is available.

Lumbar puncture may be helpful if ultrasonography is unavailable. The red blood cell count is typically high, with a protein concentration of 250 to 1,200 mg/dL. Later, the CSF becomes xanthochromic, and there may be a low glucose concentration.

Management

Prevention

The most effective prevention strategy is avoidance of premature birth. When preterm birth is inevitable, there are some prenatal and delivery room practices associated with a lowered risk of IVH. Corticosteroids given antenatally, at a dose of two 12-mg intramuscular injections of betamethasone at 24-hour intervals, reduce risk of IVH. Delayed clamping of the umbilical cord (30-60 s) has been associated observationally with a reduction in the relative risk of IVH, although a recent large trial showed no effect of delayed clamping on death or major morbidity. Maternal transport to a perinatal center before delivery reduces risk of IVH in very low birth weight infants as compared with infant transport after delivery. Tocolytic therapy may be associated with reduced risk of severe IVH.

General measures of neonatal care are widely accepted to reduce risk of IVH in the postnatal period. Resuscitation should be prompt and hemodynamic instability, hypoxia, hypercarbia, hyperoxia, and hypocarbia should be avoided. Hypotension and hypertension should be avoided and corrected (in a gradual fashion to avoid large acute changes in blood pressure). Coagulopathies and metabolic abnormalities should be corrected. Bicarbonate therapy is associated with an increased risk of IVH and should be avoided.

Therapeutic Intervention

In general, no treatment is needed for grade I and II hemorrhages, although they should be followed for progression by regular cranial ultrasonography. For grade III hemorrhage or PVHI, ongoing monitoring should be performed, with weekly head ultrasounds, daily head circumference measurement, and frequent clinical assessment for increased intracranial pressure. If there is evidence of significant lateral ventricular dilatation or increased intracranial pressure, intervention may be needed. Serial lumbar punctures can be performed, although they should be coupled with cranial ultrasonography to ensure that there is a resultant decrease in ventricular size, and it is unclear that there is advantage over conservative management. As a temporizing measure, ventricular drainage with a direct extraventricular drain or with a subcutaneous drain to a subcutaneous reservoir or a ventriculosubgaleal shunt may be helpful. Usually, if a drain is needed, eventually a permanent ventricular shunt, usually a ventriculoperitoneal shunt, will be necessary, although a third ventriculostomy may be effective as well in some cases. Every attempt should be made to delay shunting until the newborn attains as much somatic growth as possible. There are no medical interventions that have been shown to safely reduce the long-term effects of IVH.

Outcome

Grade I and II IVH usually has a good short-term outcome, with an 80% to 90% survival rate without an obvious neurologic abnormality. However, there may be long-term disorders of learning and behavior, especially with extremely low birth weight neonates (<1,000 g).

The mortality rate of grade III IVH and PVHI is approximately 20%, with 75% of the surviving infants developing posthemorrhagic hydrocephalus. Long-term prognosis worsens with decreasing gestational age and increasing severity of IVH, with higher rates of developmental delay, cerebral palsy, bilateral deafness, and bilateral blindness associated with more severe bleeds and extreme prematurity. Some infants with PVHI survive without disability, especially when the infarctions are small.

PERINATAL ASPHYXIA/HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Epidemiology

Depending on the definitions used, perinatal asphyxia in developed countries affects 3 to 8 newborns per 1,000 live births and causes moderate to severe hypoxic-ischemic encephalopathy (HIE) in 0.5 to 1 per 1,000 live births. Globally, 10% to 60% of neonates with HIE die, and 25% have long-term neurodevelopmental difficulties.

Pathobiology

Most commonly, HIE is associated with severe maternal hypotension, uterine rupture, placental abruption, and placental or umbilical cord dysfunction. In addition, there may be associated hypoxic cardiopulmonary, hepatic, or renal injury.

Brain pathology depends on the level of maturity at the time of the insult as well as the duration and location of the insult. In infants injured less than 32 weeks' gestation, PVL is commonly seen because of the vulnerability of late oligodendroglial precursors. After 36 weeks' gestation, hypoxic lesions are frequently located in the cerebral gray matter, deep gray nuclei, brainstem, and Purkinje cells of the cerebellum.

On a cellular and molecular level, hypoxia-ischemia acutely causes neuronal loss in the cerebral sulci, often with edema and infarction. Chronically, there is neuronal loss and astrocytosis, with possible atrophy, cystic encephalomalacia, ulegyria (cortical scarring resulting in deep sulcal atrophy), status marmoratus (altered myelination of the corpus striatum, giving a marble-like appearance), and cerebellar atrophy. Energy failure from hypoxia stems from loss of mitochondrial function, which can be confirmed by measuring increased lactic acid levels in the CSF or by magnetic resonance spectroscopy (MRS).

TABLE 137.1 Apgar Scores[a]

	Score of 0	Score of 1	Score of 2
Color	Blue or pale, entire body	Blue at extremities, body pink	No cyanosis
Heart rate	Absent	<100	>100
Reflex irritability	No response to stimulation	Feeble cry or grimace when stimulated	Cry or pull away when stimulated
Muscle tone	None	Some flexion	Flexed arms and legs
Respiratory effort	Absent	Weak, gasping, irregular	Strong, lusty cry

[a]Adapted from Apgar V. A proposal for a new method of evaluation of the newborn infant. *Curr Res Anesth Analg*. 1953;32(4):260-267.

There is accompanying membrane depolarization, an increase in neurotransmitter release, as well as excessive activation of glutamate receptors. Consequently, there is excitotoxic cellular injury, leading to an increase in intracellular calcium that leads to a cascade of pathologic pathways leading to secondary cell death. In addition, there is oxidative stress, which produces reactive oxygen species and subsequent reactive nitrogen radicals, also contributing to cell toxicity. After the anoxic insult, many cells undergo reoxygenation and reperfusion. Reperfusion contributes further to oxidative stress by producing more reactive oxygen species and further cellular injury.

Clinical Manifestations

The initial presentation of HIE is typically low Apgar scores, which translate into bradycardia, depressed respiration, diminished responsiveness, and decreased muscle tone (**Table 137.1**). One of three clinical patterns then evolves: (1) mild: awake, irritable, hyperalert with jitteriness, dilated pupils, increased deep tendon reflexes, and normal muscle tone; (2) moderate: lethargy with depressed deep tendon reflexes, frequently with seizures; and (3) severe: apathy, with severe hypotonia, poorly reactive pupils, an absent Moro reflex, depression or coma, and seizures. There is usually clinical improvement with the mild and moderate cases as the newborns become more alert, improve their tone, and are able to feed. Seizures or therapy for seizures may delay recovery. Newborns with severe encephalopathy will usually become stuporous, develop frequent seizures, respiratory depression, brainstem abnormalities, and may show signs of decerebration. They become unresponsive and lose sucking reflexes and the Moro response, and even with vigorous supportive and anticonvulsant therapy, 20% to 30% of these newborns die. If the neonate survives, seizures usually stop after 48 to 72 hours, and there is usually some recovery.

Diagnosis

Other causes of encephalopathy should be distinguished from HIE in the newborn period. The American College of Obstetricians and Gynecologists summarized signs that would likely result in HIE in infants greater than 35 weeks' gestation: Apgar score less than 5 at 5 and 10 minutes, cord pH less than 7.0 and/or base deficit ≥12 mmol/L, consistent brain injury seen on MRI or MRS, multisystem organ failure, as well as a sentinel hypoxic/ischemic event and nonreassuring fetal heart rate patterns LEVEL 1.[1] Multisystem organ failure consistent with HIE includes renal, hepatic, or cardiac dysfunction; hematologic abnormalities; metabolic derangements such as low serum glucose or sodium or elevated CSF lactate; and/or gastrointestinal injury. All of these criteria lie on a continuum, so, for example, worsening acidemia increases the likelihood of an intrapartum hypoxic injury.

Certain patterns of brain injury seen in neuroimaging of late preterm or term infants are commonly seen in HIE, including parasagittal injury in an arterial watershed distribution and/or injury to the deep gray nuclei (**Figs. 137.2** and **137.3**). Neuroimaging, alternatively, may reveal another cause of encephalopathy, such as a developmental brain malformation or a focal area of infarction. Brain MRI is the most sensitive imaging modality for most lesions and usually yields the most useful information, although it requires transport, monitoring, and support. If available, an MRS can be useful for diagnosis of HIE if a lactate peak is seen. Head CT is useful for detecting intracranial hemorrhage and brain calcifications but is less sensitive for detecting mild brain edema or white matter injury, which is somewhat obscured because of the high water content of the newborn white matter. The posterior fossa is not adequately imaged with CT because of bony artifact. Cranial ultrasonography can be done at the bedside but is not very sensitive for detection of white matter abnormalities or lesions in the outer cerebral cortex.

Along with revealing seizure activity that may be inapparent clinically, EEG can be helpful to indicate the degree of HIE: indications of severity include a burst-suppression pattern and/or a relatively inactive background. Amplitude-integrated EEG, while not as sensitive as standard EEG, may show low voltage in the setting of severe HIE and is able to detect some if not all seizure activity.

Management

Because multiple organ systems are involved in addition to the brain, management and therapeutic measures include maintenance of physiologic homeostasis, including providing adequate ventilation, maintenance of perfusion and metabolism, avoidance of brain edema, and seizure control. Therapeutic hypothermia for 72 hours, with a target rectal temperature of 33 to 35 degrees, has been shown in multiple randomized controlled trials to lower mortality and major neurodevelopmental disability in term and late preterm infants with moderate or severe HIE LEVEL 1.[2] There are some adverse effects of hypothermia, including an increase in sinus bradycardia and in thrombocytopenia, but generally, hypothermia is well tolerated. Hypothermia must be initiated within 6 hours after delivery, so it is essential that infants are transferred immediately to a center with expertise. In less developed countries, low-technology therapeutic hypothermia (using cooling bags or packs) has been shown to reduce neurologic morbidity and

FIGURE 137.2 Magnetic resonance imaging of full-term infant with birth asphyxia (from ruptured uterus). **A:** Inversion recovery sequence shows increased intensity within thalami and basal ganglia. **B-D:** Diffusion-weighted imaging shows restricted diffusion in the ventrolateral thalami, lentiform nuclei, cerebral peduncles, and perirolandic cortex. (From de Vries LS, Groenendaal F. Patterns of neonatal hypoxic-ischaemic brain injury. *Neuroradiology*. 2010;52[6]:555-566.)

mortality, albeit with less robust evidence than with electrical cooling systems.

Outcome

Long-term prognosis of HIE depends on the extent of brain injury. Therapeutic hypothermia has improved neurologic prognosis. Most infants with mild HIE have a normal outcome. Children with severe HIE who survive the neonatal period usually have low cognitive ability and scholastic achievement, serious motor disability, and epilepsy. Children with moderate HIE form a heterogenous group, depending on how the outcomes are measured and how the degree of encephalopathy is defined.

NEONATAL SEIZURES

Epidemiology

Neonatal brains are particularly susceptible to seizures because of a relative abundance of excitatory neurotransmitters and the relative underdevelopment of inhibitory systems. Seizures occur

FIGURE 137.3 Magnetic resonance imaging of full-term infant born with severe anemia, showing watershed pattern of injury. **A:** T2-weighted sequence shows loss of cortical ribbon, with increased signal intensity in corpus callosum. **B:** Apparent diffusion coefficient map shows decreased signal intensity in posterior watershed areas, splenium of corpus callosum, and optic radiation. (From de Vries LS, Groenendaal F. Patterns of neonatal hypoxic-ischaemic brain injury. *Neuroradiology*. 2010;52[6]:555-566.)

in 1 to 3.8 per 1,000 newborns and are often an urgent clinical problem requiring prompt diagnosis and treatment.

Pathobiology

The vast majority of neonatal seizures are due to specific etiologic causes rather than epileptic syndromes. The most common causes are encephalopathy (often HIE) in term infants and IVH in premature babies. Other important causes include other hemorrhage (intracerebral, subdural, subarachnoid), infection (meningitis, encephalitis, or intrauterine), infarction, metabolic causes (hypoglycemia, hypocalcemia, hypomagnesemia), chromosomal anomalies, cerebral malformations, neurodegenerative disorders, inborn errors of metabolism (eg, glycine encephalopathy, urea cycle defects, phenylketonuria, maple sugar urine disease, lactic or organic acidurias), and maternal drug withdrawal or intoxication. Some seizures are responsive to vitamin treatment, including vitamin B_6, pyridoxal phosphate, and folinic acid. There has been a decrease in seizure frequency from transient metabolic causes or infection, most likely because of the advances in neonatal care over the past few decades.

On a molecular and cellular level, both animal models and human studies indicate that the developmental regulation of excitatory and inhibitory synaptic networks play a crucial role in the greater susceptibility of neonates to seizures. In particular, both α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid and *N*-methyl-D-aspartate subtypes of glutamate receptors, which are excitatory, have high expression, and are expressed with subunit composition enhancing excitability of neuronal networks in the period around birth both in humans and in animal models. Additionally, the inhibitory class of γ-aminobutyric acid receptors are underexpressed during this time period.

There are three well-recognized neonatal epilepsy syndromes as classified by the International League Against Epilepsy: benign neonatal familial convulsions (BFNS) (which may be further classified into benign familial neonatal epilepsy, benign familial neonatal-infantile epilepsy, and benign familial infantile epilepsy—refer to Chapter 143), early myoclonic encephalopathy (EME), and early infantile epileptic encephalopathy (EIEE, or Ohtahara syndrome). In addition, there are benign neonatal seizures (with multiple names including "fifth-day fits"), which frequently do not require long-term therapy. Identified genes for BFNS, a dominantly inherited condition, include *KCNQ2* and *KCNQ3*, coding for voltage-gated potassium channels, and *PRRT2*, coding for a presynaptic protein involved in neurotransmission. There is evidence that carbamazepine and oxcarbazepine are effective treatments for BFNS. There are multiple etiologies of EME and EIEE, usually a severe metabolic cause for EME or a structural lesion for EIEE.

Clinical Manifestations

Seizure semiology and EEG features of neonatal seizures differ from those of older children and adults. Consequently, classification schemes for seizures in older children and adults are not appropriate for neonates. Neonatal seizure classification schemes most often rely on dominant clinical features. Focal clonic, focal tonic, and some myoclonic seizures have associated ictal EEG discharges. Other paroxysmal movements, such as generalized tonic posturing and motor automatisms (mouthing, pedaling, and rotatory arm movements), have unreliable or inconsistent EEG equivalents and may reflect etiologies other than seizures such as HIE. Generalized tonic-clonic seizures do not occur in newborns because of the immaturity of the cerebral white matter. In addition, many neonatal seizures are only seen on EEG (are subclinical or nonconvulsive), and so EEG monitoring is important for both identification and management.

Diagnosis

As with older patients with seizures, history is essential, especially details about the pregnancy, delivery, and family history. Head circumference, the presence of congenital anomalies, neurocutaneous markings, and organomegaly are all relevant findings. The neurologic exam should also note any abnormal posturing or unusual movements.

Laboratory evaluation should focus first on common metabolic or infectious disorders that are treatable—serum should be studied for levels of glucose, calcium, magnesium, sodium, and acid-base levels as well as culture. The CSF should be evaluated for meningitis and hemorrhage. An EEG should be done promptly if there are abnormal movements or unexplained behavioral changes. Continuous EEG should be done if available, as there can be seizures without clinical manifestations. Ultrasound may identify hemorrhage and hydrocephalus. Amplitude-integrated EEG may be able to detect seizures, although localization is limited and some seizures may be missed. A CT also shows hemorrhage and hydrocephalus and, in addition, demonstrates parenchymal calcifications and major cerebral malformations. An MRI is usually necessary to detect more subtle developmental abnormalities, such as lissencephaly, polymicrogyria, or cortical dysplasia.

Timing of the first seizure may aid in the diagnosis. Seizures due to severe brain malformations, intracerebral hemorrhage, and hypoxic-ischemic injury occur within 24 to 48 hours. Seizures caused by infection and inborn errors of metabolism typically begin later in the first week of life. Seizures due to drug withdrawal usually occur in the first 3 days (eg, alcohol or short-acting barbiturates) but may not appear for 2 to 3 weeks (eg, methadone).

Seizures must be distinguished from other paroxysmal phenomena that occur in newborns, including jitteriness, which can be triggered or stopped by manipulation of a limb; benign sleep myoclonus; dyskinesias (eg, seen commonly with severe bronchopulmonary dysplasia); and the movements that occur during rapid-eye movement sleep. Brief, generalized, tonic postures that occur with poor cerebral perfusion or with resolving encephalopathies are usually not epileptic seizures, and they respond poorly or not at all to antiepileptic drugs.

Management

Etiology of seizures is a crucial determinant for choosing an appropriate treatment protocol. If there is a metabolic or infectious cause, for example, there may be specific therapies to address the seizures. Pyridoxine and pyridoxal-5′-phosphate may be effective treatments for seizures refractory to conventional antiepileptic medications. Treatment of metabolic causes of neonatal seizures is presented in Table 137.2.

First-line anticonvulsant therapy for neonatal seizures has traditionally been phenobarbital, followed by fosphenytoin (preferred over phenytoin because of fewer cardiac side effects) and short-acting benzodiazepines such as intravenous lorazepam and midazolam. Increasingly, levetiracetam is being used because of

TABLE 137.2 Treatments for Metabolic Causes of Seizures

Cause	Treatment	Maintenance
Hypoglycemia	10% glucose IV 2 mL/kg	8 mg/kg/min
Hypocalcemia	10% calcium gluconate (100 mg/kg or 1 mL/kg IV) infused over 5-10 min, checking HR and infusion site, repeated in 10 min if no response OR Calcium chloride (20 mg/kg or 0.2 mL/kg)	Add calcium gluconate to IV solution.
Hypomagnesemia (may be associated with hypocalcemia)	50% solution IM 0.25 mL/kg or 125 mg/kg; repeat every 12 h until normalized	
Pyridoxine-responsive seizures	Pyridoxine 100 mg IV or pyridoxal phosphate 30 mg/kg/d divided 3 times a day	Pyridoxine 15-18 mg/kg/d and folinic acid 3-5 mg/kg/d
Pyridoxal phosphate-responsive seizures	Pyridoxal phosphate 30 mg/kg/d divided 3 or 4 times a day for 3-5 d and folinic acid 3-5 mg/kg/d	Pyridoxal phosphate 30 mg/kg/d divided 4 times a day

Abbreviations: HR, heart rate; IM, intramuscular; IV, intravenous.

its favorable side effect profile and ease of use. Lidocaine can be used second line as long as there are no contraindications (eg, congenital heart disease or pretreatment with fosphenytoin). Midazolam can also be used second line or as a treatment for status epilepticus. Topiramate may also be helpful for refractory seizures. Recommendations are to start with one anticonvulsant, and increase levels to maximum tolerance if needed, before starting with another anticonvulsant. Treatment of acute symptomatic neonatal seizures is presented in Table 137.3.

Outcome

Prognosis usually depends on etiology, and, as discussed in the preceding text, it is essential to address and remedy the underlying cause of the seizures if possible. The HIE, severe IVH, and cerebral malformations may be associated with poor outcomes, depending on severity. An interictal EEG showing a suppression-burst pattern, a low-voltage background, and/or continuous multifocal epileptiform discharges frequently correlates with disabling brain damage.

Approximately 15% to 30% of neonates with seizures will develop epilepsy. There has been a decrease in overall mortality during the past few decades from neonatal seizures, from approximately 40% to 20%, although the prevalence of long-term neurodevelopmental sequelae has been unchanged at approximately 30%, perhaps because sicker infants are surviving the acute illness but then developing chronic manifestations. There is also some question about whether seizures directly cause brain injury, in particular when there is already an underlying defect in energy metabolism such as in HIE.

TABLE 137.3 Treatment of Acute Symptomatic Neonatal Seizures[a]

Medication	Dosage	Notes
Phenobarbital	Load: 20-30 mg/kg IV, repeated once as needed; maintenance: 4-6 mg/kg/d divided twice a day (target serum level 40-60 μg/mL)	Side effects: respiratory depression, depressed level of consciousness, hypotension, hypotonia, hepatotoxicity, blood dyscrasia, skin rash
Fosphenytoin (and phenytoin)	Load: 20 mg/kg IV; maintenance: 5-8 mg/kg/d divided twice or 3 times a day (may need four times a day) (target level 20 μg/mL); may need to check free concentration (target level 1-2 μg/mL)	Cardiovascular, CNS, cutaneous side effects, which are less often seen with fosphenytoin compared with phenytoin. Variability in pharmacokinetics may result in inconsistent serum levels.
Levetiracetam	Load: 40-60 mg/kg IV; maintenance: 40-60 mg/kg/d divided twice or three times a day	Pharmacokinetics incompletely understood for neonates
Lorazepam	Load: 0.05-0.1 mg/kg IV	Side effects: respiratory depression, depressed consciousness, hypotension; myoclonus in neonates with low birth weight
Midazolam	Load: 0.15 mg/kg IV and then continuous infusion (1 μg/kg/min, titrating to effect, maximum 2-5 μg/kg/min)	Side effects: respiratory depression, depressed consciousness, hypotension
Topiramate	Load: 10 mg/kg/d divided twice a day, increase in 2 d by 5 mg/kg/d divided twice a day; goal dose 5-6 mg/kg/d	May be helpful for refractory seizures; no intravenous form is available; may result in metabolic acidosis and/or weight loss/appetite suppression
Lidocaine	Load: 2 mg/kg over 10 min, then continuous infusion 7 mg/kg/h for 4 h, then 3.5 mg/kg/h for 12 h, then 1.75 mg/kg/h for 12 h; initial infusion 3.5 h rather than 4 h if being treated with therapeutic hypothermia	Side effect: arrhythmia; should only be given in ICU setting with continuous cardiac monitoring. Avoid concurrent treatment with proarrhythmic drugs such as phenytoin. Avoid in patient with congenital heart disease and if patient has received phenytoin or fosphenytoin (because of arrhythmia risks).

Abbreviations: CNS, central nervous system; ICU, intensive care unit; IV, intravenous.

STROKE AND SINUS VENOUS THROMBOSIS

Epidemiology

Acute symptomatic perinatal stroke can be classified into three clinical groups (with incidence): arterial-ischemic stroke (70%), sinus venous thrombosis (20%), and hemorrhagic stroke (10%). The incidence is approximately 10-fold higher than in childhood stroke in general. In retrospective studies, the prevalence of perinatal ischemic stroke has been found to be approximately 1 per 3,500, but this prevalence is undoubtedly an underestimate because it is based in part on database searches, which may not account for all cases.

Pathobiology

Pathophysiologic mechanisms leading to neonatal ischemic stroke include embolism, arteriopathy, or thrombosis. Most commonly, there is an infarction in the distribution of the middle cerebral artery, more commonly on the left. Neonates are at particular risk for thromboembolism because of multiple factors, including placental pathology or the normal thrombosis of placental vessels seen at birth; right-to-left shunts that may result from a patent foramen ovale or another congenital heart lesion; or indwelling umbilical vessel catheters, commonly used in neonatal intensive care units. Prothrombotic states, either from a systemic condition such as infection or from an inherited coagulation disorder, may also play a contributory role.

Hemorrhagic stroke may result from conversion of an ischemic infarction or may be caused by a bleeding diatheses or a vascular anomaly.

Sinus venous thrombosis may result from placental conditions resulting in a prothrombotic state, or from a prothrombotic disorder. Most thromboses occur in the superior sagittal or transverse sinus, and there is frequently infarction, which may be hemorrhagic. There may be associated dehydration and/or sepsis/meningitis.

Clinical Manifestations

Arterial ischemic stroke frequently presents with seizures, with contralateral focal seizures if there is unilateral cerebral infarction. There may also be hemiparesis, which may appear as a subtle asymmetry of spontaneous movements. There may be a normal neonatal course, however, with hemiparesis presenting only after many months. Sinus venous thrombosis usually presents with seizures and/or alteration of consciousness. Hemorrhagic stroke also presents with alteration of consciousness and seizures as well as focal weakness, apnea, or hypotonia.

Diagnosis

Head CT, or, preferably, MRI/magnetic resonance angiography, will show complete or branch infarcts, usually in the middle cerebral artery distributions. An infarct may be detected early with diffusion-weighted imaging. Magnetic resonance angiography can also be helpful if there are congenital vascular anomalies or carotid artery dissection.

In Sinus Venous Thrombosis (SVT), MRI/magnetic resonance venography or CT may show the "empty delta" sign and/or associated stroke or hemorrhage (Fig. 137.4). There may also be hemorrhagic infarction bilaterally in the parasagittal regions if there is sagittal sinus thrombosis (the most common form of SVT) or hemorrhage involving deep structures with deep venous thrombosis. There may also be seen IVHs, together with thalamic and internal capsule infarction.

If the infant presents with seizures, a thorough evaluation for systemic causes, such as infection, inborn errors of metabolism, or toxicity should be performed. The EEG may show focal attenuation, slowing, and/or epileptiform discharges. An echocardiogram should be done to evaluate for a congenital anomaly or a thrombus. Prothrombin and activated partial thromboplastin times should be measured if there is hemorrhage. The placenta can be examined to assess for clots or infarcts.

Hypercoagulability should be evaluated in the setting of ischemic stroke and sinus venous thrombosis. The workup includes maternal studies for lupus anticoagulant, anticardiolipin antibody, and antinuclear antibodies. The placenta should be examined for infarcts or clots. Protein S, protein C, and antithrombin III can be tested in the newborn period but should be retested at 3 to 4 months of age because newborns normally have low values of these proteins. Genetic analysis can be performed for factor V Leiden and prothrombin G20210A mutations. Homocystinuria, if not part of regular newborn screening, can be assessed with the maternal homocysteine concentration or methylene tetrahydrofolate reductase mutations.

Management

Supportive care for stroke includes maintenance of adequate oxygenation; treatment of acidosis, electrolyte disturbances, dehydration, and anemia; and antibiotic or anticonvulsant treatment if needed. For arterial ischemic stroke, treatment with anticoagulants or antiplatelet agents is restricted to patients with a documented cardioembolic source or recurrent arterial ischemic stroke, or patients who are at risk for recurrent stroke because of severe thrombophilic disorders.

Historically, there has been controversy regarding anticoagulation therapy for SVT, although there is now growing evidence supporting its safety, and there is also evidence that treatment reduces the occurrence of clot propagation. Current recommended guidelines from the American College of Chest Physicians (AACP) suggest anticoagulation for 6 weeks up to 3 months.

Outcome

Long-term prognosis for ischemic stroke depends on the location and extent of the ischemic injury. Hemiparesis occurs in 25% to 30% of infants with unilateral infarction and is more often seen when there is infarction of the entire middle cerebral artery territory. Milder neuromotor dysfunction occurs in another 30% with unilateral damage. Epilepsy occurs in 10% to 40% of patients with acute perinatal stroke. Cognitive impairment occurs in 20% to 25% of patients with unilateral infarction, with a worse risk if there is bilateral infarction or a large injury. The involvement of deep gray nuclei worsens cognitive outcome.

Outcome of sinus venous thrombosis varies. Most neonates (93%-97%) survive the immediate neonatal period. Motor deficit occurs in approximately 60% of survivors, with cognitive impairment in approximately 25% to 50% and epilepsy in 20% to 40%.

Hemorrhagic stroke outcomes are also quite variable. Mortality ranges from 4% to 25%, and there may be subsequent cerebral palsy, cognitive impairment, and/or epilepsy.

FIGURE 137.4 **A,D:** Head computed tomography, age 6 weeks. Extensive dural venous thrombosis involving the superior sagittal sinus, straight sinus, and internal cerebral veins, with hemorrhage extending intraventricularly. **B:** Magnetic resonance imaging of brain, age 6 weeks. Susceptibility-weighted consistent with hemorrhage in the periventricular, subcortical, and deep white matter. **E:** Sagittal view of postgadolinium T1 magnetic resonance imaging showing filling defect in confluence of sinuses. **C,F:** Magnetic resonance venography, age 6 weeks. Extensive dural venous sinus thrombosis with partial flow in the bilateral transverse sinuses with patency of the internal jugular veins.

PERIVENTRICULAR LEUKOMALACIA

Epidemiology

A PVL is a focal injury, usually from infection or ischemia, to the cerebral white matter, in the periventricular region; occasionally, there is more diffuse injury. It is more commonly seen in premature infants, especially in infants less than 32 weeks gestational age, although it can be seen in term infants as well. Prevalence based on ultrasound diagnosis ranges from 5% to 15% of very low birth weight infants, but the prevalence is higher when MRI, which is a more sensitive imaging modality, is used.

Pathobiology

The cerebral white matter of premature neonates is particularly vulnerable to injury because of a number of factors: (1) diminished vascularization and subsequent reduced blood flow in the periventricular area; (2) inadequate cerebral vascular autoregulation (with reduced cerebral perfusion in the setting of hypotension); and (3) the susceptibility of preoligodendrocytes (the predominant cell in white matter at early gestational ages and the precursor to normal myelin-producing cells) to injury and cell death from glutamate toxicity, which stems from hypoxia. Maternal infection, which is a risk factor for premature birth itself and lead to umbilical cord funisitis, or neonatal sepsis, is associated with PVL because of cytokines such as interleukin-1β, interleukin-6, and tumor necrosis factor α producing free radicals, which then activate astrocytes and microglia, which in turn release reactive oxygen species, toxic to the susceptible preoligodendrocytes.

Clinical Manifestations

Hypomyelination is seen in periventricular fibers descending from the frontal lobes to the peripheral neurons in the legs. Consequently, the classical presentation is spastic diplegia and cerebral palsy, which may not present in the newborn period. The involvement of the visual radiations in the posterior white matter can result in visual impairment. There may also be ex vacuo ventriculomegaly, with associated decreased gray matter volume, which may cause behavioral abnormalities and subnormal IQ scores.

Diagnosis

Ultrasonography typically reveals echodensities adjacent to the lateral ventricles, throughout the periventricular region, and usually evolves over time, with potential development of echolucent cysts within weeks and then ventriculomegaly over months.

More sensitive is MRI, which can detect more subtle diffuse white matter injuries or noncystic lesions. Diffusion-weighted imaging may allow for earlier detection of PVL or white matter injuries.

Management

Infants with PVL need to be closely monitored for development of neurologic sequelae, with the appropriate therapy provided for spasticity, cognitive, and visual complications.

Outcome

Infants with more extensive injury and ventriculomegaly are more likely to experience more severe motor and cognitive difficulties. Cyst formation is more likely to result in cerebral palsy. White matter injuries are a risk factor for cortical abnormalities and reduction in gray matter volume.

138 Nervous System Formation and Malformation

Gary D. Clark

KEY POINTS

1. Nervous system development involves a series of distinct, yet overlapping phases.
2. Malformations of the nervous system can best be understood in the context of the phases have gone awry.
3. Genetic disorders give insight into the molecular processes underlying phases of nervous system development.

OVERVIEW

Induced by underlying mesodermal structures, such as the notochord, and inhibited by surrounding ectodermal tissue, the nervous system begins as a thickened layer of poorly differentiated cells in the developing ectodermal layer of a 14-day human embryo. By 21 days, ridgelike structures have formed in the lateralmost aspects of the neuroectoderm, begin to appose and to close in multiple closure sites, first in the cervical region. This forms a tubelike structure, termed the *neural tube*, and this closure is normally complete by 26 days, before most women know that they are pregnant. Errors in this process lead to myelomeningoceles (L1 and more rostral) and encephaloceles.

At the most caudal end of this tube is a mixed cell mass of ectoderm and mesoderm, termed the *caudal cell mass*, which is induced by the presence of the neural tube to form the sacrum, filum terminale, the conus medullaris, and the cauda equina. Errors in these processes lead to tethered spinal cords, caudal regression, fatty filum terminale, sacral pits and tracks, and other sacral defects.

The neural crest cells form from the extreme lateral aspects of the neuroectoderm and give rise to many of the sensory ganglia of cranial and spinal nerves in addition to the sympathetic chain and other structures.

Once the neural tube is completely formed, patterning or segmentation of this tube leads to the formation of the well-described vesicles of the developing nervous system (prosencephalon, mesencephalon, and rhombencephalon). The prosencephalon divides in the midline to two telencephalic vesicles that will become the cerebral hemispheres. Precursors lining the ventricles of the developing nervous systems become postmitotic and migrate radially to populate developing structures such as the cortex. Axons sprout and cross the midline to form the corpus callosum and thereby connect the two developing hemispheres. Neurons extend axons to connect in a very deliberate and use dependent fashion to the appropriate targets. To understand nervous system malformations, some additional genetic, molecular and basic neurobiology insight is needed.

This chapter summarizes normal and abnormal human central nervous system (CNS) formation and describes the genetic aberrations that cause congenital malformations of the CNS. Much of human CNS development is inferred from animal studies and from abnormal developmental processes. Without being exhaustive, the proteins believed to be involved in the individual components of CNS development and those involved in pathologic alterations of normal development will be listed. The functions of some of the genes responsible for abnormal development can be surmised by examining the pathologic consequences. Hence, one is able to correlate genetic abnormalities with developmental neuropathology. Other genes and molecules involved in abnormal human CNS formation have well-studied counterparts in animals that provide insight into their function in humans.

The study of the genetics of human development is a rapidly growing area, and important new genetic mechanisms are being described often. Although the information regarding human genes involved in normal and abnormal brain formation was as up-to-date as possible at the time that this chapter was written, important new insights into the genetics of human CNS development have likely been made since. Please visit Online Mendelian Inheritance in Man (OMIM) for more current information (http://www.ncbi.nlm.nih.gov/omim). As is the convention for the time that this chapter is written, terms such as *pathogenic variant* for those previously termed *mutation* are used herein.

Emphasis is placed on important information for the clinician in this chapter; space limitations and lack of current applicability to clinical neurology limit the amount of information that can be communicated. Instead, the covered pathologic entities are presented in the context of the developmental processes that are believed to have gone awry. Disorders previously categorized as migration abnormalities might, on the basis of new genetic insights, be found in the discussion of cellular differentiation or segmentation, for example. As further insights are made into human brain developmental disorders leading to neurologic disorders, the following categorization scheme will likely undergo alteration.

FORMATION OF NEUROECTODERM

The human brain is formed from the *neuroectoderm*, a placode of cells that are induced by the underlying notochord to differentiate from the ectoderm, a process beginning at 14 to 18 days of gestation. The nature of the inducible factor(s) (actually inhibiting factors because they inhibit bone morphogenic protein 4) involved in this process remain unknown. The molecular action of these molecules probably is similar to that of the retinoids, binding to a nuclear receptor to promote or suppress specific genes.

NEURAL TUBE CLOSURE

Primary Neurulation

The neuroectoderm placode develops ridges (folds) laterally and begins to approximate in the region of the future medulla at 22 days of gestation, before most women are aware they are pregnant. This closure, a process known as *neurulation*, results in a tube that continues to extend by the process of approximation of the neural folds in multiple locations rostrally and caudally until a complete neural tube is formed at 28 days of gestation, with the latter period marking the end of caudal neural tube closure (future spinal cord). The rostral neural tube, which closes at approximately 24 days gestation, serves as the foundation for further brain development; the caudal end of the tube forms the spinal cord (Fig. 138.1).

Although the specific molecules and genes involved in the processes of neural tube closure in the human are unknown, clearly a combination of genetic and environmental factors leads to disorders of these processes. Studies in mice suggest that a codeletion of *Paxl*, a gene for a *transcriptional factor* that mediates notochord signaling, and *Pdgfra*, the platelet-derived growth factor alpha gene, may lead to a spina bifida–like phenotype.

Certain ethnic groups experience a higher incidence of neural tube closure defects than do others, and genetic disorders with an apparent autosomal recessive inheritance that include neural tube defects have been described. In addition, teratogens are involved in neural tube pathology. The most notable teratogens for the neurologist are the anticonvulsants valproate and carbamazepine, each of which imposes a risk of 1% to 6% for a neural tube defect in offspring exposed in utero to these common drugs. Whereas folate supplementation appears to prevent neural tube defects in large population studies, this vitamin may or may not be protective when these disorders are associated with the aforementioned anticonvulsants. Given the likely lack of harm of short-term treatment with folate, it seems prudent to offer this vitamin (400-4,000 μg daily, depending on risk factors) to women of childbearing age who are on anticonvulsants.

Specific Neural Tube Defects

In the human, multiple genes and factors are likely involved in the pathogenesis of disorders of neural tube formation and closure. The human disorders of neural tube closure include craniorachischisis (a complete failure of neural tube closure along the entire neuraxis), anencephaly (a failure of anterior neural tube closure), myeloschisis (a failure of posterior, neural tube closure), spina bifida (myelomeningocele, a failure of closure of a portion of posterior neural tube), and encephalocele (a partial defect in anterior neural tube closure). Fetal recognition of myelomeningocele with correction in utero prior to 26 weeks' gestation can dramatically alter the need for subsequent ventriculoperitoneal shunting (reduced by 42%) and reduces the incidence of intellectual disability.The risk is to the mother, and this risk is being lowered by new relatively less invasive techniques.

Encephaloceles

Encephaloceles (brain substance outside of the skull) and meningoceles (meninges and cerebrospinal fluid only) vary in location, in the amount of brain involved, and, therefore, in the clinical manifestations of the lesions. In most cases, the neural tube is closed, and the gyral pattern of the protruding brain appears normal. Occipital encephaloceles are more common in eastern Asia and nasal encephaloceles are more common in the rest of the world. One should avoid nasogastric tube placement in the situation of a nasal mass in a newborn owing to the possibility of a nasal encephalocele; it is possible in this situation to place the tube in the brain substance.

Meckel Syndrome

Meckel syndrome, a genetic disorder that involves an occipital encephalocele, cerebellar malformations (molar tooth anomaly—see discussion below in Joubert syndrome), microcephaly, renal dysplasia (polycystic kidneys), polydactyly, retinal dystrophy, and other malformations, appears to be caused by pathogenic variants in genes involved in ciliary function. Meckel syndrome is allelic with Joubert syndrome and the same genetic aberrations are present in both disorders. Most of these disorders are

FIGURE 138.1 A: Notochord plate induces the neuroepithelium to differentiate from surrounding ectoderm. At the periphery of the neuroepithelium, neural crest forms. B: Neural tube closes. C,D: Rostral neural tube is induced by ventral notochord (Sonic Hedgehog and other factors) to split into two telencephalic vesicles that will become the cerebral hemispheres. (Drawings by Nathan Lucy.)

inherited in an autosomal recessive fashion, although some are inherited in a dominant fashion and others X-linked dominant or recessive. The genes involved are part of a ciliary complex that determines cell polarity and are important for the migration of early neurons in the posterior fossa.

EMBRYONIC NERVOUS SYSTEM SEGMENTATION

Flexures of the rostral neural tube delineate the primary vesicles of the developing nervous system; these are designated as the hindbrain (rhombencephalon), the midbrain (mesencephalon), and the forebrain (prosencephalon). These primary vesicles then further subdivide into the secondary vesicles that later will form the adult brain structures. The hindbrain consists of the metencephalon and myelencephalon; these structures will become the pons, the cerebellum, and the medulla oblongata of the adult. Rostrally, the mesencephalon will become the midbrain of the adult. The forebrain is further divided into the telencephalon and the diencephalon. The telencephalon will become the cerebral hemispheres, and the diencephalon will become the thalamus and hypothalamus of the adult.

Transcriptional Factors and Homeobox Genes

Regional specification of the developing nervous system is an important step in human CNS development and is likely under the control of a number of genes that encode transcriptional factors and of a number of molecules that influence these genes. Many of these genes were first described in the fruit fly, *Drosophila*, and are involved in the regional specification of the fly embryo. Not surprisingly, the function of the proteins encoded by the comparable genes in mammals differs considerably from that in fruit flies, but the general role of these proteins appears to be that of regional specification of clones of cells destined to form structures in the fully developed nervous system.

Transcriptional factors are proteins with distinct sequences that participate in DNA binding and thus influence DNA. In *Drosophila*, at least two transcriptional factors encoding homeobox genes, empty spiracles, have been shown to specify brain structures in humans. In the rudimentary structures of mutant flies that are devoid of *ems*, there seems to be a failure of regional specification of a clone of cells that are destined to form that structure. In humans, pathogenic variants in the comparable gene *EMX2* result in schizencephaly, a cleft in the cortical mantle. The clefts in this disorder extend from the pia to the ventricle and are lined with a polymicrogyric gray matter (see the discussion in "Polymicrogyria" section). The pia and ependyma are usually in apposition, especially in severe cases. The defect is termed *open-lip* if the cleft walls are separated by cerebrospinal and *closed-lip* if the walls appose. These clefts may be unilateral or bilateral and the prognosis appears to be dependent on location, bilateral occurrence, or extent of the lesion. Bilateral schizencephaly is associated with intellectual disability and spastic cerebral palsy; affected patients often are microcephalic. Seizures almost always accompany severe lesions, especially the open-lip and bilateral schizencephalic clefts. The exact frequency of seizures in patients with the less severe lesions is uncertain, or is the incidence of asymptomatic schizencephaly. Most patients in whom schizencephaly is diagnosed undergo neuroimaging because of seizures. Therefore, there is an ascertainment bias in favor of a universal occurrence of seizure in this disorder. Hence, patients with schizencephaly who do not have epilepsy might exist, but the malformation remains undetected because no imaging is done. With fetal imaging, asymptomatic schizencephaly has been noted (personal observation, Fig. 138.2).

Seizure type and onset may vary in this disorder. Patients may experience focal or generalized seizures. Some will present with infantile spasms. The onset varies from infancy to the early adult years. Seizures may be easily controlled or may be recalcitrant to standard anticonvulsant therapy.

Improvements in neuroimaging have enhanced the recognition of these disorders and have broadened the spectrum of the radiographic appearance of schizencephalic lesions. The lesions may occur in isolation or may be associated with other anomalies of brain development. An especially common association is made between septo-optic dysplasia and schizencephaly: As many as 50% of patients with septo-optic dysplasia also have schizencephaly.

Other genes for transcriptional factors have been described in the mouse. *Pax3*, *PaxS*, *Pax6*, *Dlxl*, *Dlx2*, *Dbx*, and the *Hox* genes are found in specific brain regions. In general, the *Pax* genes tend to be expressed in the midbrain, and the *Dlx* genes tend to be expressed in the ventral forebrain, ventral telencephalon, and dorsal telencephalon; *Dlx2* is important for the genesis of GABAergic interneurons from the median ganglionic eminence. The *Hox* genes seem to specify the neuromeres and rhombomeres of the hindbrain.

Furthermore, in an interesting link to the ventral inductive events described later, when applied to proliferating cells at critical times in development, the protein Sonic Hedgehog can alter the expression of the homeobox genes. This ties the inductive proteins to the expression of homeobox genes and gives a hint as to the mechanisms involved in inductive processes.

A gradient of retinoic acid in a rostral (less) to caudal (more) fashion seems to be important for *Hox* and other patterning gene expression patterns in the hindbrain, neck, and other structures of the head. Retinoic acid activity also decreases Sonic Hedgehog signaling (see "Ventral Induction" section). Because of their affect on Sonic Hedgehog signaling, retinoids are highly regulated and should not be given to women who may become pregnant.

Septo-Optic Dysplasia

Septo-optic dysplasia (de Morsier syndrome) is a disorder characterized by absence of the septum pellucidum, optic nerve hypoplasia, and hypothalamic dysfunction. This disorder should be considered in any patient who exhibits any of these findings, and all such patients should have hypothalamic function screening. Fifty percent of patients with septo-optic dysplasia have schizencephaly. Although this is a rare disorder, genetic syndromes with this phenotype and with some risk of recurrence have been described. For instance, pathogenic variants in homeobox gene expressed in embryonic stem (ES) cells, *HESX1*, have caused a dominantly inherited disorder in siblings. There is evidence that this disorder may result from early, nonspecific insults to the developing fetal brain. This disorder can be suspected in utero but magnetic resonance imaging (MRI) of the fetus may be necessary to assure a proper diagnosis. The prognosis for development is highly variable, with learning, intellectual, and motor impairments often described. Asymptomatic patients probably only come to medical attention if there are needs for neuroimaging. Pathogenic variants in *COL11A2* and *PAX6* have also been described as a cause of this disorder. Because most of the genes related to this phenotype are undiscovered and no genetic panels exist, it is recommended that clinicians consider exome sequencing in order to delineate the recurrence risk, if any, in a family.

VENTRAL INDUCTION

Normal Prosencephalon Division

The telencephalon is formed by medial division of a rostral single tubelike structure (prosencephalon); the two vesicles (telencephalon) formed in this division become the two cerebral hemispheres. The ventral and anterior portion of this division is induced by midline facial structures and the notochord via soluble factors. Abnormalities of this induction and division lead to midline abnormalities of the brain such as holoprosencephaly. These disruptions of normal development occur before 42 days of gestation.

Sonic Hedgehog, which was described first in *Drosophila* as a soluble factor (protein) that influences dorsoventral patterning of the developing embryo, is probably the most important of the soluble factors influencing ventral induction. Sonic Hedgehog is expressed in the notochord (also in ventral forebrain and floor plate—future facial structures), interacts through a well-defined signaling pathway that includes *PTCH*, a human homolog of *patched*, and alters the expression of transcriptional factors (homeobox and other related gene products).

Other molecules of interest in this inductive process are the retinoids (discussed previously in segmentation), which are lipids capable of crossing membranes and have been shown to exist in gradients across embryos. Retinoic acid can alter the pattern of transcriptional factors in neuroepithelial cells, and it can also downregulate Sonic Hedgehog, perhaps explaining some of the midfacial defects and holoprosencephaly seen in retinoid embryopathy. Also, cholesterol and cholesterol-derived lipids serve as a cofactor for Sonic Hedgehog, thus perhaps explaining telencephalic cleavage difficulties in Smith-Lemli-Opitz syndrome (7-dehydrocholesterol reductase deficiency).

Disorders of Ventral Induction

Holoprosencephaly

The holoprosencephaly syndromes are heterogeneous disorders of ventral induction and telencephalic cleavage that result from a failure of the prosencephalic vesicle to medially cleave normally. At least three forms of this disorder have been described: alobar, semilobar, and lobar. In the alobar form, the telencephalic vesicle completely fails to divide, producing a single horseshoe-shaped ventricle, sometimes with a dorsal cyst, fused thalami, and a malformed cortex. In the semilobar form, the interhemispheric fissure is present posteriorly, but the frontal and, sometimes, parietal lobes continue across the midline. In the lobar form, only minor changes may be seen: The anterior falx is absent, the frontal lobes and horns are hypoplastic, partial fusion of the thalamus, and the genu of the corpus callosum may occur. Holoprosencephaly is the most common human malformation leading to miscarriage.

Because Sonic Hedgehog and patched are expressed in the developing face, it is not surprising that holoprosencephaly is associated with a spectrum of midline facial defects. These include cyclopia, in which there is a single central eye and a supraorbital proboscis; ethmocephaly, in which the nose is replaced by a proboscis located above hypoteloric eyes; cebocephaly, in which hypotelorism and a nose with a single nostril are seen; and premaxillary agenesis, with hypotelorism, a flat nose, a single frontal incisor, and a midline cleft lip.

Only children who have the semilobar and lobar forms are known to survive for more than a few months. An infant affected with the severe form is microcephalic (unless aqueduct stenosis and hydrocephalus are present), hypotonic, and visually inattentive. In infants with the less severe forms of holoprosencephaly, myoclonic seizures frequently develop and, if the infant survives, autonomic dysfunction, failure to thrive, psychomotor retardation, and atonic or spastic cerebral palsy often are present. Some infants with the lobar form may be only mildly affected. Pituitary defects may be associated with these malformations and may result in neuroendocrine dysfunction.

Holoprosencephaly has been reported to be associated with maternal diabetes, retinoic acid exposure, cytomegalovirus, and rubella. Chromosomal abnormalities associated with this disorder include trisomies 13 and 18; duplications in 3p, 13q, and 18q; and deletions in 2p, 7q, 13q, and 18q. Autosomal dominant forms exist in which the pathogenic variant is in the Sonic Hedgehog gene on chromosome 7. In this form, the clinical features vary. In its mildest form, presence of a single central incisor, attention deficit disorder, or a choroid fissure coloboma may be the only clinical manifestation of autosomal dominant holoprosencephaly (Fig. 138.3).

FIGURE 138.3 Failure of telencephalic cleavage. Holoprosencephaly in a fetus at 32 weeks' gestation. Note the single ventricle with no division of the cerebrum into hemispheres on a coronal view **(left panel)**. On a sagittal view **(right panel)**, a dorsal cyst is noted that is typical for alobar holoprosencephaly.

NEURONAL AND GLIAL PROLIFERATION

Normal Cell Proliferation

Lining the interior of the newly developed telencephalic vesicles is a proliferative, primitive neuroepithelium. Neuroepithelial processes extend from the ventricular surface to the pial surface, and the nuclei of the primitive neuroepithelial cells move from the cortical surface in a premitotic phase to a mitotic phase near the ventricle. Cells divide at the most ventricular aspects of the developing telencephalon and, after division, move back toward the pial surface. The pial processes of neuroepithelial cells near the ventricle often will detach from the cortical surface before a new cycle begins.

Neuroepithelial cells divide in so-called proliferative units such that each unit will undergo a specific number of divisions resulting in the appropriate number of cells for the future cortex. Abnormalities in the number of proliferative units or in the total number of divisions can lead to disorders of brain manifested by abnormal brain size and, therefore, an unusually small (microcephaly) or large head (macrocephaly). Disorders in which too many cells are generated in the proliferative phase result in megalencephaly (large brain) or, if proliferative events go awry on only one side of the developing cortex, hemimegalencephaly. Once the appropriate complement of cells is generated in the proliferative phase, the cells that will become the neurons of the cerebral cortex become postmitotic and are referred to as *neuroblasts*. Others undergo a programmed cell death, apoptosis. The genetics of apoptosis are best characterized in the simple nematode *Caenorhabditis elegans*. Approximately 10% of the cells generated during development of this worm will undergo apoptotic or programmed cell death. Pathogenic variants leading to smaller or larger numbers of surviving cells result in smaller or larger nematodes, respectively. The molecular characterization of these pathogenic variants has led to identification of a number of "death" genes and of genes that prevent apoptosis. The mammalian counterparts of the nematode death genes encode enzymes that are cysteine aspartate–specific proteases, also known as *caspases*. At least one function of such enzymes is that of an interleukin-converting enzyme, common in the inflammatory response of the body. These enzymes have been shown to promote neuronal death; in addition, when an animal is produced without caspase 3, a larger than normal brain results.

Disorders of Neuronal and Glial Proliferation

Microcephaly

Although primary familial microcephaly may be a normal variant, in the classic symptomatic form, clinical and radiologic examinations reveal a receding forehead, flat occiput, early closure of fontanelles, and hair anomalies such as multiple hair whirls and an anterior cowlick. Neuroimaging may show small frontal and occipital lobes, open opercula, and an uncovered cerebellum. The cortex may appear malformed (polymicrogyria, pachygyria, diminished white matter).

Neurologic findings also vary. Only mild psychomotor retardation may be noted, sometimes associated with pyramidal signs, or more severe intellectual disability, seizures, and a hypotonic cerebral palsy might be present. Primary microcephaly is seen in many genetic syndromes and, in its isolated form, may be autosomal recessive. Autosomal dominant and X-linked transmission has also been reported. *Microcephaly vera* is the term applied to this genetic form of microcephaly. Affected children present with a head circumference that is usually more than 2 standard deviations below the mean, hypotonia, and intellectual disability. They later show mental retardation, dyspraxias, motor incoordination, and occasionally seizures.

Destructive lesions of the forming brain, such as those caused by teratogens and by infectious agents, also may result in microcephaly. Teratogens of note are alcohol, cocaine, and hyperphenylalaninemia (maternal phenylketonuria). Intense radiation exposure in the first trimester can cause microcephaly. Microcephaly and intracranial calcifications are likely due to well-recognized in utero infections caused by cytomegalovirus, toxoplasmosis, Zika, or the human immunodeficiency virus, among others.

Although now usually recognized in utero, patients with pathologic microcephaly or pathologic macrocephaly have been, in the past, identified by their pediatricians. Neuroimaging may reveal an etiology in such patients. Because multiple genetic or teratogenic etiologies must be considered, one must use neuroimaging as a clue to possible etiologies (presence of malformations, calcifications, etc.). The prognosis varies greatly and depends on the etiology. Familial microcephaly and familial macrocephaly with benign outcomes have been described.

Megalencephaly and Hemimegalencephaly

The terms *megalencephaly* and *hemimegalencephaly* refer to disorders in which the brain volume is greater than normal (not owing to the abnormal storage of material); usually, the enlarged brain is accompanied by macrocephaly, or a large head. Although considered by some to be a migration disorder, the increase in brain size in these disorders appears to be attributable to errors in neuroepithelial proliferation, as the microscopic appearance of the brain is that of an increase in number of cells (both neurons and glia) and in cell size.

Typically, patients are noted to have large heads at birth and may manifest an accelerated head growth in the first few months of life. Children with megalencephaly or hemimegalencephaly may come to medical attention when presenting with seizures, a developmental disorder (intellectual disability), hemihypertrophy, or a hemiparesis (opposite the affected hemisphere). Seizures vary both in onset and in type and usually are the most problematic symptom, sometimes necessitating hemispherectomy or callosotomy.

Approximately 50% of patients with linear sebaceous nevus syndrome have hemimegalencephaly associated with *HRAS* or *KRAS* somatic-mosaic pathogenic variants. Many patients with hypomelanosis of Ito also have hemimegalencephaly. The neuropathologic and clinical pictures in these conditions appear to be identical to the isolated hemimegalencephalies. Interestingly, the genetic aberrations suggest an upregulation of the mammalian target of rapamycin (mTOR) pathway via a downregulation of phosphoinositol kinase 3 (PI3 kinase).

Microscopic examination of the affected brain usually reveals an increase in cellularity, large bizarre neurons, enlarged glia, cortical lamination defects, and heterotopias. The cortex usually is thickened, and malformed neurons are disturbed in polarity. Interestingly, the cytologic basis for the increase in brain size may be the abundant cytoplasm of individual cells.

NEURONAL DIFFERENTIATION

Normal Differentiation

At the time of neuronal differentiation, the neural tube consists of four contiguous layers: (1) the ventricular zone, which gives rise to neurons and all the glia of the CNS; (2) the subventricular zone, which is the more superficial layer and is the staging area from which postmitotic neurons begin to differentiate and to migrate; (3) the intermediate zone, which is the contiguous, more superficial zone and which is destined to become the cortical plate and the future cerebral cortex; and (4) the marginal zone, which is the outermost zone and is composed of the cytoplasmic extensions of ventricular neuroblasts, corticopetal fibers, and the terminal processes of radial glia (which, at this time, are completely spanning the neural tube).

Differentiation of neuroepithelial cells begins in the subventricular layer at approximately gestational day 26. Neuroepithelial cells were destined to become neurons at the time of the final mitotic division of the neuroepithelial cell precursor, before moving to the subventricular zone, the staging area for neuronal migration. At this point, these neuroblasts lack electrically polarized membranes as would commonly be seen in neurons. The fate of the neuroblast is likely determined before this final mitosis has occurred because the postmitotic neuroblast has the properties of many neuron types. The older, larger pyramidal cells are the first cells to be born and probably differentiate early in order to act as targets or barriers in the migration of the nervous system.

No disorders of solely neuronal differentiation have yet been identified, although some disorders may be found to fit into this category. For instance, premature neuroblast differentiation could result in an inability of these cells to migrate and thus could manifest as a migration abnormality. The megalencephaly and hemimegalencephaly syndromes may yet be found to be the results of disturbances in differentiation, as discussed earlier. Disorders such as tuberous sclerosis, in which both tumor development and areas of migration abnormalities are seen, seem to be a differentiation disorder due to upregulation of mTOR. The brain manifestations of this disorder include hamartomas of the subependymal layer (tubers), areas of cortical migration abnormalities (cortical dysgenesis), and the development of giant-cell astrocytomas in upward of 5% of patients. Two genes for tuberous sclerosis have been identified: *TSC1* (encodes for hamartin) has been localized to 9q34 and *TSC2* (encodes for tuberin) has been localized to 16p13.3. Both proteins suppress mTOR, and loss or dysfunction lead to overactivation of this important protein in development. The frequency of gene abnormalities in tuberous sclerosis patients has been estimated to be almost equally distributed between *TSC1* and *TSC2*. Interestingly, recently type IIb cortical dysplasias were found to harbor human papillomavirus (HPV) 16 and its oncogenic protein E6, which exerts its effect by upregulating mTOR by, in part, depressing *TSC2*. Therefore, at least some cortical dysplasias are preventable by HPV vaccination of parents prior to conception.

NEURONAL MIGRATION

Normal Migration

At the most rostral end of the neural tube in the 40-day-old fetus, the first mature neuron arrives at the developing cortical surface. These first neurons are the *Cajal-Retzius cells*, which are the major neurons of the cortex by day 43. Cajal-Retzius cells, along with corticopetal nerve fibers, form a so-called preplate. These cells will be the major cell type of the most superficial layer of the cerebral cortex, layer I. At the same time that the Cajal-Retzius cells are arriving at the most superficial layer of cortex, other pioneering neurons differentiate and form a so-called subplate. The pioneering neurons of the subplate and the preplate act as the police officers of the developing nervous system and define the limits of the developing cortical plate, which will become the six-layered cortex of the adult brain. Most of the cells of the subplate will die postnatally in a programmed cell death (see earlier discussion of apoptosis).

Near the end of the proliferative phase of neurodevelopment, billions of postmitotic neurons are poised to begin the trip to the cortical surface and to form the cortical plate. This tremendous number of neurons accomplishes this task, for the most part, by attaching to and migrating along radial glia (radially spanning from ventricle to pial surface) in a process known as *radial migration* (**Fig. 138.4**). In the process of migration, the deepest layer of the cortical plate forms before the other layers. Therefore, the first neurons to arrive at the future cortical plate are layer VI neurons. More superficial layers of cortex then are formed such that the neurons of layer V migrate and pass the neurons of layer VI; the same process occurs for layers IV, III, and II. The cortex therefore is formed in an inside-out fashion.

The molecules and the interactions between neurons and glia are extremely important in this process of neuronal migration.

FIGURE 138.4 Neuronal radial migration in cortical development. **Upper left** depicts a single cortical vesicle stained for glia. Glia radially project from the ventricle to the cortical surface. The **right figure** depicts the apposition of the migrating neuron to a radial glial cell. Cells migrate past their predecessor to deposit in an inside out fashion.

Reelin, the protein involved in the migration mouse mutant, reeler, appears to be one such important molecule. Reelin appears to promote an attachment of neurons to glia and, when abnormal, as in the mouse mutant reeler, it leads to an inverted cortex such that the most superficial neurons are the first to arrive and the later arriving neurons are deeper. This mouse mutant cortex appears to be due to an abnormally adhesive interaction between neurons and glia. Additional molecules that appear to act in an adhesive manner are laminin, astrotactin, L1 antigen, fibronectin, neural cell adhesion molecules (NCAM), and adhesion molecule on glia.

Neuroblast movement on radial glia involves an extension of a leading process, a neural outgrowth having an orderly arrangement of microtubules. *Microtubules* are cytoskeletal elements with a polymerizing (positive) and a depolymerizing (negative) end. They serve as the major structural element that gives shape to long neural processes. When microtubules depolymerize, or slide, long neural processes are shortened. Shortening of the leading process of migrating neurons has been associated with forward movement of the soma of migrating neurons in vitro. Cytoskeletal changes in leading processes have been purported to be responsible for this shortening and somal movement.

A possible mode of movement in neuronal migration on glia would be the attachment of the neuron to a matrix secreted by either the glia or the neurons. This matrix is likely to consist of the aforementioned adhesion molecules. The attachment of the neuron is through *integrin* receptors, cytoskeletal-linking membrane-bound recognition sites for adhesion molecules. That attachment serves as a stronghold for the leading process and soma of the migrating neuron. Shortening of the leading process owing to depolymerization or shifts of microtubules results in movement of the soma relative to the attachment points. This theory of movement of neurons also includes a phase of detachment from the matrix at certain integrin receptors so that the neuroblast can navigate successfully along as much as 6 cm of developing cortex (the maximum estimated distance of radial migration of a neuroblast humans). Finally, the movement of cells must stop at the appropriate location, the boundary between layer I and the forming cortical plate. Therefore, some stop signal must be given in order for the migrating neuroblast to detach from the radial glia and begin to differentiate into a cortical neuron. This process is deficient in such disorders as cobblestone lissencephalies (discussed in the following text).

Other forms of neuronal migration occur in brain development. Some evidence exists for a tangential migration of neurons in the cortex and in the early granule cell migration in the cerebellum. A so-called chain migration of neurons on other neurons occurs in the formation of the olfactory bulbs. In this chain migration, neuroblasts from the subventricular zone of the lateral ventricle migrate to the olfactory bulb through a sheath of glial cells, but the actual migration occurs on other neurons.

Cortical Neuronal Migration Disorders

Many clinical entities are associated with neuronal migration disorders. In some, abnormalities are limited to the nervous system, but, in others, malformations involving other organs also are present. The responsible genetic mechanism has been identified in some of these disorders, and new genetic mechanisms are being identified regularly. Although the role of the gene product in producing many of these migration disorders

may not yet be entirely clear, the disorders provide important clues to mechanisms that are responsible for normal brain development.

Modern neuroimaging techniques, particularly MRI, have allowed the recognition of major migration disorders. Some of these disorders are associated with typical clinical features that might alert the clinician to the presence of such abnormalities even before imaging is obtained. In other disorders, the clinical features are so varied that a strong correlation between imaging and clinical presentation does not exist. High-field MRI and other research techniques may further refine the clinician's ability to refine diagnoses.

Lissencephaly

Although the term *lissencephaly* (smooth brain) refers to the external appearance of the cerebral cortex in those disorders in which a neuronal migration aberration leads to improper number of neurons at the surface of the cortex (Fig. 138.5), the most important observation in such cases is the thickened cortex with neurons in what should be white matter. In such deficits of migration, Gyri and sulci do not form properly because the cortical-cortical attractive forces that result from strong associations are decreased, owing to improper axon pathways (ie, the targets for synapses are malpositioned). It is important to note that the term *lissencephaly* is applied to cortical disorders in which there is a thickened cortex (migration deficit) and a cortical surface abnormality; rarely is there a completely smooth brain. At least two types of lissencephaly have been identified: type I, or classic lissencephaly, and type II, or cobblestone lissencephaly. This classification is based on both the external appearance of the brain and the underlying histology.

Type I (Classic) Lissencephaly

Type I lissencephaly most often accompanies the *Miller-Dieker syndrome*. In this disorder, an inadequate radial migration of neurons appears to have taken place. The cortex is described as being composed of a four-layer abnormal sequence, consisting of an outer molecular layer (layer 1), which is similar to normal layer I; a disorganized cellular layer of neurons near the normal location for the outer cortex (layer 2) (cells that should be in layers II-VI of the normal cortical plate); a cell-sparse zone (layer 3); and a heterotopic zone of neurons that have been arrested in neuronal migration (layer 4). The most extensive layer in this lissencephalic sequence is layer 4, the heterotopic zone. The neurons and cells of this zone have the appearance of cells that would normally be in layers II-IV of the normal cortical plate; however, these neurons are highly disorganized. Therefore, the later waves of neuronal migration that form the outer cortical plate appear to be those most affected by the migration abnormality in this disorder.

FIGURE 138.5 Lissencephaly spectrum. **Top panels** are from a patient harboring a *LIS1* deletion. To the left is an axial T1 magnetic resonance image demonstrating agyria posteriorly and pachygyria anteriorly. To the right is a lateral sagittal T1 magnetic resonance image from the same patient demonstrating the same gradient of posterior worse than anterior malformation. Bottom panels are from a female with a *DOUBLECORTIN* (*DCX*) mutation demonstrating the so-called double cortex (subcortical band heterotopia).

Hallmarks on imaging are a lack of opercularization (covering of the sylvian fissure), large ventricles with colpocephaly (fetal-like configuration of the occipital horns), and agyria or pachygyria (see Fig. 138.5). The corpus callosum is almost never absent, and the posterior fossa has a normal appearance on neuroimaging. Head size typically is in the low-normal range at birth, but most patients develop microcephaly owing to a decreased rate of brain growth over the first year of life. Nearly all patients with this disorder will develop seizures within this first year, and more than 80% of them will have infantile spasms. This seizure frequency is far greater than that seen in other neuronal migration disorders.

In the Miller-Dieker syndrome, facial dysmorphism, cardiac abnormalities (40%), sacral abnormalities (70%), deep palmar creases, and, in male patients, genital abnormalities (70%) may be seen. The sacral abnormalities include deep sacral dimples, sacral pits, and sacral tracks. Facial abnormalities include upturned nares, a short nose, a thin, "pouty" upper lip, a long philtrum, micrognathia, and bitemporal hollowing. Although the bitemporal hollowing may be the result of the underlying brain abnormality, the other facial features would be difficult to explain on the basis of the brain abnormality alone. Therefore, these abnormalities are believed to result from deficits of genes near the lissencephaly gene on the seventeenth chromosome. Larger deletions of the distal short arm of chromosome 17 appear to result in the full Miller-Dieker phenotype, whereas microdeletions of just the lissencephaly gene, *LIS1*, result in isolated lissencephaly. Therefore, a deletion in the lissencephaly gene appears to be sufficient for the brain abnormalities, but other genes (14-3-3) must be deleted for the full phenotypic manifestations of the Miller-Dieker syndrome to be seen.

Miller-Dieker lissencephaly is one of the migration disorders of brain in which the responsible genetic defect has been identified. By both molecular and cytogenetic techniques, deletions in the terminal portion of one arm of chromosome 17 can be found in approximately 90% of Miller-Dieker lissencephaly cases. These patients typically have dysmorphic features and other congenital anomalies (see earlier discussion). The deletions of the terminal part of chromosome 17 in these cases have included microdeletions, ring 17 chromosome, pericentric inversions, and a partial monosomy of 17p13.3. These genetic abnormalities often are the result of an inherited unbalanced translocation from a parent with a balanced translocation involving this region of chromosome 17; multiple mechanisms of inheritance similar to this have been described for this disorder. Of course, a parent with a balanced translocation of chromosome 17p is at a greatly increased risk of having another child with Miller-Dieker lissencephaly. In families that are affected in this manner, screening with amniocentesis can be performed in subsequent pregnancies.

Current chromosomal microarray testing will detect deletions of *LIS1* and of the neighboring *14-3-3* gene, thus genetically distinguishing Miller-Dieker syndrome from isolated lissencephaly. Some patients with isolated lissencephaly (no facial, skeletal, or cardiac abnormalities) also have small deletions of the terminal portion of the short arm of chromosome 17. Therefore, some researchers suspected that within one deleted region of chromosome 17 was a gene that, when deleted, was sufficient to result in the lissencephaly phenotype. In 1993, the human gene for this form of lissencephaly was identified as *LIS1*.

The protein encoded by *LIS1* has 99% homology to a 45-kD subunit of a bovine brain platelet-activating factor acetylhydrolase (in humans *PAFAH1B1*). Subsequently, depletion of this protein has been demonstrated in the brains of patients with Miller-Dieker syndrome and with isolated lissencephaly. Interestingly, whereas the message for *LIS1* in mice is expressed ubiquitously, the LIS1 protein product has been localized to the neuropile, Cajal-Retzius cells, and ventricular neuroepithelium at the time of human neuronal migration. However, it is not the lack of enzyme activity that leads to the brain malformation; rather it appears that the catalytic units of this enzyme complex regulate the available level of LIS1 protein.

The brain malformations in LIS1 deficiencies are usually worse posteriorly as compared with X-linked lissencephaly, which is worse anteriorly as discussed in the following text. However, in Miller-Dieker syndrome, the malformation may be equally severe anteriorly and posteriorly, thus making a distinction phenotypically difficult. This lesion can be detected in utero, but late in the pregnancy. The life expectancy is dependent on the severity of the neurologic impairment.

X-linked lissencephaly looks nearly identical to the *LIS1* deletion form of this disorder: Patients have classic lissencephaly, and the neurologic presentation is the same. However, the malformation is usually worse anteriorly, and the skeletal and other anomalies seen in the Miller-Dieker syndrome are not noted in this form of lissencephaly. In addition, X-linked lissencephaly occurs almost exclusively in boys. Girls who are heterozygous for the same gene have band heterotopia. Women with band heterotopia have been noted to give birth to boys with lissencephaly.

The *X-linked lissencephaly–band heterotopia syndrome* has been linked to Xq22.3.145,146. In female patients, the less severe phenotype is likely attributable to random X inactivation, such that in a variable percentage of cells, normal gene expression is seen and, in the remaining cells, the pathogenic variant for X-linked lissencephaly, *DOUBLECORTIN*, is expressed. Doublecortin is a microtubule associated protein that appears to stabilize the cytoskeletal structure. It appears that X-linked lissencephaly is a cell-autonomous disorder, in that the cell expressing the abnormal X chromosome manifests aberrant migration or disturbed substrate on which cells can migrate.

The band heterotopia or double-cortex syndrome is a unique form of a neuronal migration defect that almost exclusively occurs in girls and is allelic with X-linked lissencephaly in boys. In this disorder, a circumferential, thick band of tissue is isointense with cerebral gray matter located within what should be the white matter of the hemispheres (see Fig. 138.5). This band is most obvious in the frontocentroparietal regions in keeping with the anterior worse than posterior gradient in this disorder. The inner and outer margins at its interface with the adjacent white matter usually are smooth. The overlying gyral pattern may vary from normal cortex to abnormal sulcation. This anomaly represents incomplete neuronal migration. The exact mechanism is unclear, but possibilities include a lack of separation of the migrating neuron from the radial fiber or an arrest on the path to a normal cortical location.

Patients with band heterotopia typically present with seizures and a developmental disorder. The seizure type is variable, and the onset of epilepsy usually is between 2 months and 11 years of age. Patients may present with infantile spasms or, even though the migration abnormality is diffuse, with focal seizures. Control of the epilepsy varies, some patients being

controlled with monotherapy and others being entirely refractory to all agents.

Most patients with the X-linked lissencephaly–band heterotopia syndrome (double cortex) have impaired intellectual development that ranges from severe retardation to low-normal IQs; there is a report of a girl with an IQ of 91. Generally, individuals with this syndrome are less impaired than are patients with other diffuse neuronal migration defects such as lissencephaly. Patients in whom seizures are of later onset generally have less developmental impairment. Neurologic findings include mild dysarthria and mild bilateral pyramidal syndromes.

Type II (Cobblestone) Lissencephaly

In type II lissencephaly, the brain may have a smooth appearance or may exhibit polymicrogyria and pachygyria. The underlying cortical histology is that of a bizarre arrangement of neurons. Typically, in the most affected areas, normal cortical plate formation is not evident. Rather, bizarre whirls of cells are found. In addition, cells seem to penetrate the molecular layer and may spill into the subarachnoid space as if part of a volcanic eruption. This deposition of neurons in the subarachnoid space imparts a cobblestone street–like appearance to the brain surface; thus, the term *cobblestone lissencephaly* has been used to describe the cortex in these disorders. The Walker-Warburg, muscle-eye-brain, and Fukuyama muscular dystrophy syndromes are genetically distinct. Abnormalities that may or may not be seen in these disorders include muscular dystrophy, ocular anterior chamber abnormalities, retinal dysplasias (abnormal electroretinogram and visual-evoked responses), hydrocephalus (usually of an obstructive type, requiring shunting), and encephaloceles. The Walker-Warburg syndrome or muscle-eye-brain disorder might be diagnosed even if the ocular examination and muscle biopsies are normal. On MRI, an abnormal white matter signal, hypoplastic brainstem and cerebellum, and a thickened falx suggest the Walker-Warburg diagnosis (see Fig. 138.7). Neuroimaging of the muscle-eye-brain disorders might reveal focal white matter abnormalities. This disorder and other cobblestone lissencephalies have been diagnosed in utero.

In the cobblestone lissencephaly spectrum, despite the widespread cortical abnormalities, only one-third of patients develop seizures. The typical presentation is that of a child with marked hypotonia, macrocephaly (obstructive hydrocephalus), and eye abnormalities. Depending on the degree of brain and of muscle involvement, this disorder may not be compatible with life. Long-term survival is rare. Syndromes accompanying type II lissencephaly include the Walker-Warburg syndrome, hydrocephalus, agyria, retinal dysplasia, with or without eye (anterior chamber) abnormalities (HARD-±-E) syndrome, muscle-eye-brain disease, and Fukuyama muscular dystrophy. These are all the result of recessive inheritance of pathogenic variants in extracellular matrix proteins or in the cell receptors for the extracellular matrix.

Fukuyama muscular dystrophy is distinguished from the Walker-Warburg–like syndromes by the severity of the muscular dystrophy, by the cortical malformation that includes polymicrogyria and frequently by Japanese inheritance. This disorder is seen more often in Japan than in the Western hemisphere, probably because it is the result of a founder pathogenic variant (a viral transposon insertion) in a gene termed *FUKUTIN*. Patients typically present with evidence of a neuronal migration defect (cobblestone lissencephaly) with polymicrogyria, hypotonia, and depressed reflexes.

TABLE 138.1 Cobblestone Lissencephaly Disorders

Gene	Inheritance	Phenotypes
POMT1	AR	Cobblestone lissencephaly, muscular dystrophy
POMT2	AR	Intellectual disability, "mild brain malformations," muscular dystrophy
FUKUTIN	AR	Fukuyama muscular dystrophy, cobblestone lissencephaly, Walker-Warburg syndrome, limb-girdle muscular dystrophy
FKRP	AR	Walker-Warburg syndrome, muscle-eye-brain, cardiomyopathy, limb-girdle muscular dystrophy
LARGE	AR	Brain malformations, congenital muscular dystrophy
ISPD	AR	Cobblestone lissencephaly, limb-girdle muscular dystrophy

Abbreviation: AR, autosomal recessive.

Not surprisingly, patients with other pathogenic variants of *FUKUTIN* have been described to have muscle-eye-brain and even cardiac abnormal phenotypes. The protein fukutin interacts with laminin, an extracellular protein expressed in brain, muscle, and eyes, and with alpha dystroglycans on muscle membranes. There is further interaction with fukutin-related protein (FKRP), which seems to promote glycosylation of α-dystroglycans in coordination with fukutin; FKRP pathogenic variants may cause Walker-Warburg, muscle-eye-brain, HARD-±-E, muscular dystrophy, or may be asymptomatic. See Table 138.1 for known genes involved in cobblestone lissencephalies; only about 50% of patients have genetic aberrations identified, making the case for exome sequencing in these disorders.

All of these syndromes are accompanied by muscle abnormalities; the most extreme muscle involvement is in the Fukuyama muscular dystrophy patients. In the Walker-Warburg syndrome, the muscle abnormalities may or may not be clinically apparent (normal creatinine kinase, no apparent myopathy on clinical exam).

Kallmann Syndrome

Kallmann syndrome is an X-linked disorder characterized by anosmia and a defect in gonad development. Patients with this disorder may have other neurologic signs and symptoms, including cerebellar dysfunction and eye movement abnormalities. Therefore, abnormalities in other areas of brain, especially the cerebellum, have been suspected in this disorder. Gonadal dysfunction is thought to result from a deficiency in gonadotropin-releasing hormone. Because the neurons that produce gonadotropin-releasing hormone are derived from the olfactory plate and actually migrate back into the forebrain via the olfactory nerve, the abnormality of this hormone is likely due to an arrest in migration of the gonadotropin-releasing hormone neurons.

The gene for Kallmann syndrome has been localized to the X chromosome and appears to encode a fibronectin type III–like molecule. Because fibronectin type III has been proposed to be a neural adhesion molecule, the gene for Kallmann syndrome probably also encodes a neural adhesion molecule involved in olfactory and hypothalamic neuron migration.

Zellweger Syndrome

Zellweger syndrome is an autosomal recessive, peroxisomal disorder characterized by neuronal migration abnormalities, hepatomegaly, renal cysts, and stippled calcification of the patella. The neuronal migration defects include pachygyria and polymicrogyria, with underlying abnormalities best characterized as a nonlayered appearance of the cortex. Migration abnormalities are also noted in the cerebellum and in the brainstem in this disorder. Children with Zellweger syndrome present in the neonatal period with severe hypotonia, characteristic facies, hepatomegaly, and seizures. A mouse model of Zellweger syndrome has been produced; migration abnormalities were noted in the cerebellum and cortex, despite normal-appearing radial glia. Disturbed maturation of neurons and apoptotic neurons also are noted in this mouse model; perhaps similar mechanisms are operative in the comparable human disorder. More than 12 *PEX* genes have been implicated in Zellweger or Zellweger-like disorders; all are inherited in an autosomal recessive pattern.

Zellweger syndrome results from the body's inability to make peroxisomes owing to a deficiency of one of the 12 proteins encoded by the *PEX* genes. A number of peroxisomal enzymes are abnormal and lead to the accumulation of very-long-chain fatty acids. Therefore, testing for this disorder includes an assay of very-long-chain fatty acids.

Polymicrogyria

Polymicrogyria (many small gyri) is a disorder often considered to be a neuronal migration disorder; it is important to recognize that this malformation may result both genetic and destructive processes. The microscopic appearance of the lesion is that of too many small abnormal gyri. The gyri may be shallow and separated by shallow sulci, which may be associated with an apparent increased cortical thickness on neuroimaging. The multiple small convolutions may not have intervening sulci, or the sulci may be bridged by fusion of overlying molecular layer, which may give a smooth appearance to the brain's surface; alternatively, the brain may appear to have pachygyria.

Polymicrogyria takes two distinct histologic forms, four-layered and unlayered. The four-layer form consists of an outer layer, a neuronal layer, a cell-sparse layer, and a deeper neuronal layer. One theory is that the lower cell-sparse layer of the four-layer types represents a glial scar from laminar necrosis. On the basis of examination of fetuses in which the occurrence of the insult causing the malformation has been accurately timed, this pattern is believed to occur as a result of insults late in the first or early in the second trimester. Others believe that this is a postmigration insult resulting from distorted migration of cells through an injured area, the outcome of which is the cell-sparse layer. A cell-sparse layer between the upper and lower neuronal layers is absent from the unlayered form. Insults that occur early in the second trimester before migration is completed are believed to be the origin of unlayered polymicrogyria. Identical twin pregnancies discordant for polymicrogyria have been described; the theory being that global insults can lead to polymicrogyria. The common association of congenital cytomegalovirus infection with polymicrogyria supports the hypothesis that a destructive process can be involved in these disorders. Cytomegalovirus maternal infections during pregnancy is a common cause of polymicrogyria and microcephaly; Zika virus appears to cause similar malformations.

Polymicrogyria has also been associated with genetic and chromosomal disorders. It is found in disorders of peroxisomal metabolism such as Zellweger syndrome (see discussion earlier) and neonatal adrenoleukodystrophy. It has also been associated with the Bloch-Sulzberger syndrome, Meckel-Gruber syndrome, thanatophoric dysplasia, and Fukuyama congenital muscular dystrophy. Familial bilateral frontal polymicrogyria and bilateral perisylvian polymicrogyria have been reported. If no identifiable cause of the polymicrogyric malformation is found, the recurrence risk may be that of an autosomal recessive disorder (25%) or an X-linked disorder in boys. A bilateral parasagittal parieto-occipital polymicrogyria has also been described. Multiple chromosomal deletions and duplications, including X-linked potential inheritance, have been described. Multiple recessively inherited disorders have also been identified, including GPR56 and WDR62 pathogenic variants in families with recurrences of polymicrogyria with variable phenotypes.

The clinical picture varies depending on the location, extent, and etiology of the abnormality. Microcephaly with severe developmental delay and hypertonia may result when polymicrogyria is diffuse. When polymicrogyria is unilateral, focal deficits might be seen. Epilepsy often is present, characterized by partial-complex seizures or partial seizures that secondarily generalize. The age at presentation and severity of seizures depends on the extent of the associated pathology.

The lesions are most clearly recognized by MRI and are best noted on sagittal views. They often are recognized by the rough appearance of the surface of the cortex on a thin-cut T_2-weighted image. If MRI cuts are thick, these lesions may be confused with pachygyria. Because the genetic implications of pachygyria and polymicrogyria differ considerably, distinguishing between these two conditions is important.

Congenital Bilateral Perisylvian Syndrome

Advances in neuroimaging have led to the recognition of the congenital bilateral perisylvian syndrome, also known as the *Foix-Chavany-Marie syndrome*. The MRI demonstrates bilateral abnormalities in the opercular and perisylvian regions. The cortex is irregular, and the sylvian fissure may extend to the top of the convexity.

Striking clinical features include a pseudobulbar palsy with abnormal tongue movements, dysarthria, dysphasia, mental retardation, absent or hyperactive gag reflex, drooling, and pyramidal signs in more than 70% of the reported cases. These patients may be intellectually disabled, and nearly all have severe language disorders. Dysphagia can impair proper nutrition. Seizures are present in most of the affected patients. Several patients have had infantile spasms during the first year of life. Seventy percent of the patients experience seizures before the age of 10. The etiology of this syndrome is similar to other forms of polymicrogyria (deletions, duplications, insults [cytomegalovirus, twin pregnancies], Aicardi syndrome [see following text], and recessively inherited pathogenic variants in genes).

Heterotopias

Heterotopias are collections of normal-appearing neurons in an abnormal location, likely secondary to a disturbance in radial migration. The exact mechanism of the migrational aberration has not been established. Various hypotheses include damage to the radial glial fibers, premature transformation of radial glial cells into astrocytes, or a deficiency of specific molecules on the

surface of neuroblasts or of the radial glial cells (or the receptors for those molecules) that results in disruption of the normal migration process. Heterotopias often occur as isolated defects that may result in epilepsy only. However, when they are multiple, heterotopias might also be associated with a developmental disorder and cerebral palsy (usually spastic). In addition, if other migration defects such as gyral abnormalities are present, the clinical syndrome may be more profound. Usually, no cause is apparent. Occasionally, heterotopias may be found in a variety of syndromes, including neonatal adrenoleukodystrophy, glutaric aciduria type II, GM_2 gangliosidosis, neurocutaneous syndromes, multiple congenital anomaly syndromes, chromosomal abnormalities, and fetal toxic exposures.

Heterotopias may be classified by their location: subpial, within the cerebral white matter, and in the subependymal region. Leptomeningeal heterotopias often contain astrocytes mixed with ectopic neurons and may resemble a gliotic scar. They may be related to discontinuities in the external limiting membrane and often are associated with type II lissencephaly. These *subarachnoid heterotopias* are responsible for the pebbled appearance of the surface of the brain (therefore the name cobblestone lissencephaly). *White matter heterotopias* may be focal, subcortical, or diffuse. They may cause distortion of the ventricles and may be associated with diminished white matter in the surrounding area. When diffuse, they may take the form of a circumferential subcortical layer of heterotopic gray matter, which has been called *band heterotopia* or the *double-cortex syndrome* (see previous discussion in "Type I [Classic] Lissencephaly" section). Laminar heterotopia consists of sheets of ectopic gray matter that may be split into elongated islands. A central ovoid mass of white matter may be present within the band. Patients with this form of subcortical heterotopia have a high prevalence of developmental delay, hemiplegia, and seizures. Nodular subcortical heterotopias may be seen in association with subependymal heterotopias.

Subependymal heterotopias often are associated only with epilepsy. Most patients will have normal intelligence and no motor deficits. These heterotopias are located just beneath and abut the ependymal lining of the lateral ventricles. They may be either bilateral or unilateral and are located most often adjacent to the occipital horns and trigones and, less commonly, within the temporal horns and frontal horns. Seizure onset in patients with subependymal heterotopias is relatively late, often in the second decade, and more often affects women. The seizures may be partial complex, tonic-clonic, or focal motor. Subependymal heterotopias have been identified as an X-linked dominant syndrome linked to markers in the distal Xq28 locus, and pathogenic variants in *FILAMIN A* have been found to be causative. FILAMIN A, a cytoskeletal protein, must be important for the initiation of migration because cells are arrested in the ventricular zone. An increased incidence of spontaneous abortions, patent ductus arteriosus, spontaneous hemorrhage, and a much higher than expected incidence of female offspring are noted in affected women, suggesting that inheritance of *FILAMIN A* pathogenic variants may be lethal for male embryos. Some variants in this gene may result in male phenotypes. A syndrome marked by periventricular heterotopia, mental retardation, and syndactyly has recently been described in males.

Patients with diffuse gray matter heterotopias, whether subependymal or in the white matter, frequently are candidates for medical treatment of epilepsy. Occasionally, patients who are refractory to medical management may be considered for hemispherectomies or focal cortical resections. In the case of bilateral temporal lobe periventricular heterotopias, the prognosis for a surgical cure may be poor.

Cortical Dysgenesis

Cortical dysgenesis refers to disorders of cortical formation. In general, many of the disorders just discussed are considered to be within its spectrum. In this section, an emphasis on the focal macroscopic and microscopic lesions that do not fit into the preceding classifications are discussed.

The terms *cortical dysplasia* and *cortical dysgenesis* often are used synonymously for the same disorders. Included in these terms are not only the obvious malformations such as smooth gyri and clefts but also lesions classified as focal cortical dysplasias and microdysgenesis. Focal cortical dysplasia may involve a major part of a lobe and may be characterized by the congregation of large, bizarre neurons and abnormal glial cells in the subadjacent white matter. *Microdysgenesis* can be detected only histologically and is beyond the imaging capability of current MRI scans. It consists of unipolar and bipolar neurons under the pia, increased neurons in the first layer of the cortex, indistinct boundaries between the first and second layers of the cortex, neuronal glial heterotopias in the pia, persistence of columnar architecture of the cortex, and an increased number of neurons in the white matter. Patients with microdysgenesis are reported in series of patients undergoing epilepsy surgery. Microdysgenesis is not detected in patients with controlled epilepsy, and thus, the incidences of migration disorders and of microdysgenesis responsible for epilepsy are unknown.

Microdysgenesis was the most common migration disorder noted in a series of pathologic examinations of brain tissue removed from epileptic patients. Malformations of this type were found in 14% of epileptic brains; the frequency of other abnormalities in epileptic brains was microgyria, 4.7%; heterotopia, 15%; and pachygyria, 8%. In patients with microdysgenesis, seizure onset occurs between 2 and 20 years of age.

A surprisingly high incidence of microdysgenesis has been reported in brain tissue removed from adults to treat recalcitrant seizures. The lesions noted included ectopic neurons within the subcortical white matter in 42% of the specimens and neuronal clustering in 28%; in addition, bare areas were present within layers II to VI. Similar findings have been reported in epilepsy surgical specimens from children. Thus, microscopic abnormalities have been found in 20% to 40% of specimens from patients undergoing surgical therapy for intractable epilepsy, the most common lesions being microdysgenesis and cortical dysplasias.

As mentioned earlier, MRI has been useful in detecting migration abnormalities and generally has been found to be more sensitive than CT scanning. The MRI-apparent migration abnormalities have been detected in as many as 50% of patients who underwent epilepsy surgery. Of those patients with epilepsy alone, 6.7% had migration abnormalities; in those who had both mental retardation and epilepsy, such abnormalities were found in 13.7%. The abnormalities included pachygyria or polymicrogyria or both, schizencephaly, heterotopias, and hemimegalencephaly. Of 222 adults with temporal lobe epilepsy studied by MRI, 7.2% were found to have malformations of the temporal lobe. These malformations consisted of heterotopias, focal neocortical dysgenesis, hippocampal malformations, or a combination of various lesions.

Cortical dysgenesis has also been associated with hippocampal sclerosis, leading some to believe that hippocampal sclerosis is a disorder of brain formation. Raymond and colleagues studied 100 patients with hippocampal sclerosis diagnosed by histologic examination or MRI and found that 15 of the patients also had cortical dysgenesis. The most common abnormality was subependymal heterotopia. The cortical dysplasia was, at times, contralateral to the hippocampal sclerosis.

Clearly, migration aberrations need not be manifested by abnormal motor function; rather, epilepsy and intellectual disability might be the only clinical symptoms in these disorders.

The severity of the migration disorder correlates with clinical symptoms. Patients with milder forms of neuronal migration defects (ie, focal cortical dysplasias, heterotopias, microdysgenesis) may appear normal. Most often, migration disorders are diagnosed in patients with epilepsy, as neuroimaging is performed for seizure. These patients generally have partial seizures and normal life expectancies. Some patients with these disorders will have developmental delays, mild intellectual deficits, or spastic or atonic cerebral palsy. Profound defects are associated with more severe symptoms.

Children presenting with intractable epilepsy, significant intellectual disability, and neurologic signs more often have diffuse migration abnormalities on MRI scanning. Therefore, not surprisingly, the degree of abnormality on MRI scans correlates well with the degree of neurologic involvement. The age of onset of seizures varies from early childhood to young adult life. Generally, the severity of the seizures and the severity of the pathology correlate positively. Severe abnormalities are associated with seizures in the first year of life, whereas microdysgenesis may be associated with adult onset of seizures. Later onset seizures also tend to correlate with subependymal heterotopias.

Although the pathogenic mechanisms involved in focal dysgenesis remain poorly understood, mechanisms similar to those involved in global or more extensive migration disorders probably are operative. Therefore, definition of the pathogenic mechanisms causing these disorders is important. An important insight into the pathogenesis of focal developmental lesions may have come from the observation that the HPV 16 RNA and its oncogenic protein E6 are present in focal cortical dysplasia type IIb resected for epilepsy. This fascinating observation potentially ties HPV with tuberous sclerosis because the E6 protein encoded by HPV exerts its oncogenic effect via depression of TSC2 and AKT, thereby upregulating mTOR as occurs in tuberous sclerosis. In support of this hypothesis, cortical dysplasia type IIB also occurs in tuberous sclerosis. Indeed, other viruses could have similar effects on the developing nervous system and could explain microdysgenesis and other lesions of the nervous system described earlier.

POSTERIOR FOSSA FORMATION AND MALFORMATION

Posterior fossa malformations are best understood in terms of the normal developmental processes that have gone awry. At 4 weeks of human gestation, the hindbrain or rhombencephalon bends and divided into two vesicles, the metencephalon and the myelencephalon. The pons develops in the floor of the metencephalon and the lateral walls of the myelencephalon form the medulla oblongata. The cerebellum develops from the dorsal hindbrain (neuromere 1, rhombic lip) with contributions from the lower mesencephalon, which forms the vermis, and the metencephalon, which forms the cerebellar hemispheres. As this development progresses, mesenchymal tissue from the forming skull and meninges invade to form the choroid plexus. This invasion of mesenchymal tissue is caudal to the developing rhombic lip, and this invasion penetrates the developing fourth ventricle. The roof of the developing fourth ventricle is divided by this invading mesenchymal tissue in to two areas, the anterior membranous area and the posterior membranous area. The rhombic lip, the developing cerebellum, grows over the structures as it enlarges to form the cerebellum. As the cerebellum develops, the anterior membranous area involutes, and the posterior membranous area protrudes outward from the developing nervous system. This performs the so-called Blake's pouch cyst, which may persist normally until 4 months' gestation. Eventually, the foramina of Magendie form in the Blake's pouch cyst, and the protrusion normally involutes. The foramina of Luschka also develops around this time.

A proliferative zone of cells in the ventricular region of the rhombic lip give rise to future Purkinje cells, which migrate radially toward the surface of the developing cerebellum. At the tip of the rhombic lip, cerebellar granule cells are formed that migrate over the surface of the rhombic lip and then, in a reverse radial migration, penetrate the developing cerebellum, pass Purkinje cells, and deposit in the developing internal granule cell layer. This process of cerebellar granule cell formation occurs in the first year of human life. Prior to the formation of granule cells, other neurons are formed in the ventricular zone and migrate to the various nuclei of the brainstem.

For the purposes of this chapter, I will divide posterior fossa malformations into predominantly neuronal structural malformations and malformations of the foramina, ventricular, and transient cyst structures of the developing brain. This division is in all likelihood further defined by the genetic abnormalities that are involved in neuronal genesis, migration, and patterning (predominantly neuronal structural malformations) and those of mesenchymal support structures that are important in the formation of the transient cysts of the developing posterior fossa.

Joubert, Meckel-Gruber, and Other Ciliopathies

In the classic form, Joubert syndrome is a recessively inherited disorder with clinical features of variable intellectual impairment, respiratory rate dysregulation, oculomotor movement abnormalities (classically oculomotor apraxia), hypotonia, and ataxia. Kidney, liver, renal, and retinal abnormalities may accompany these symptoms and signs. Radiologically, Joubert syndrome is recognized by the molar tooth anomaly and accompanying vermian hypoplasia or aplasia. The molar tooth malformation results from thin cerebellar peduncles that extend dorsally at right angles to the brainstem and absence or hypoplasia of the vermis giving the appearance of roots of a molar tooth. Absence of the cerebellar peduncle decussation and disturbance of the cortical spinal tract decussation combined with brainstem nuclei abnormalities results in a thinning of the brainstem with a prominent isthmus giving the ventral brainstem the appearance of the crown of a molar tooth. Cerebellar foliation defects may be noted along with other brainstem abnormalities.

The Meckel-Gruber syndrome may include the above brainstem and cerebellar abnormalities but is distinguished by the presence of an occipital encephalocele that is usually located near the level of the torcula and may contain supratentorial contents or infratentorial contents or both. There may be syndactyly, renal, liver, retinal, or kidney pathology and the developmental outcomes are more severe than those of Joubert syndrome.

Genetically, Joubert and Meckel-Gruber are caused by recessive loss of function pathogenic variants in primary ciliary genes. The primary cilia are the polarity antennae of many cells, are not motile, or have motility functions other than to determine directionality in development.

Rhombencephalosynapsis

Rhombencephalosynapsis is fusion of the cerebellar hemispheres with absence of the vermis. The cause of this lesion is unknown but seems to result from a dorsal lack of division of the developing cerebellum. Clinical manifestations may be developmental, or this lesion may be seen in asymptomatic patients. To date, the genetics of this lesion is undetermined with the exception of an implication of *ZIC2* in a combination of holoprosencephaly and rhombencephalosynapsis noted in two half sisters concordant for a pathogenic variant in this gene. This lesion is also associated with the Gomez-Lopez-Hernandez syndrome.

Dandy-Walker

Possibly failure to form the foramina of Magendie or failure to involute the anterior membranous area results in an enlargement of the fourth ventricle thereby lifting, externally rotating and compressing the vermis. The cerebellar hemispheres are splayed outward and the torcula may be elevated. The posterior fossa is enlarged and in 80% of cases there is obstructive hydrocephalus requiring postnatal shunting from either failure to form the foramina and therefore outflow from the fourth ventricle or from compression of the aqueduct of Silvius. This lesion is associated with good neurologic outcomes if there are no accompanying distinct malformations of the brain and if not accompanying trisomy 9, 13, 18, 21 or other chromosomal aberrations. Some of the genes associated with this disorder are expressed in meninges and developing skull (*FOXC1*) and others in the dorsal cerebellum during development (*ZIC1*, *ZIC4*). The single gene defects thus far associated with this brain lesion are heterozygote deletions or loss of function mutations (Fig. 138.6).

FIGURE 138.6 Dandy-Walker malformation. **A:** Midsagittal drawing of the posterior fossa with normal fourth ventricle. **B:** Midsagittal drawing of the posterior fossa in Dandy-Walker malformation. The foramina of Magendie have not opened resulting in a large fourth ventricle that rotates, compresses, and elevates the vermis and the torcula. **C:** 21-week fetus with Dandy-Walker malformation. **D:** Dandy-Walker malformation with obstructive hydrocephalus in a newborn. (Panels A and B by Nathan Lucy.)

FIGURE 138.7 Walker-Warburg syndrome. Midsagittal magnetic resonance imaging of a fetus at 25 weeks' gestation. The ventricles are enlarged, but importantly (see *arrow*), there is a hypoplastic brainstem in a Z-like configuration.

Unfortunately, a rather loose use of the terms *Dandy-Walker* and *Dandy-Walker variant* have made the literature regarding these malformations very difficult to interpret and given the impression that these lesions carry poor prognoses; for the most part, they do not. It is my opinion that the terms *Dandy-Walker* and *Dandy-Walker variant* should be reserved for those malformations that solely involve enlargement of the fourth ventricle with its consequences such that in the case of Dandy-Walker variant, the lesion should include at least upward rotation of the vermis. An enlarged cisterna magna forms embryologically in a different fashion, although *FOXC1* is implicated in both enlarged cisterna magna and in Dandy-Walker. Furthermore, arachnoid cysts may form in the posterior fossa resulting in enlargement of the posterior fossa and even compression of developing structures, but because these form distinctly from the dilatation of the fourth ventricle in Dandy-Walker, the term *Dandy-Walker* should not be applied to these lesions or should the expectations be the same. Similarly, in the earlier described lesions of the posterior fossa that do not expand it, there may be hypoplasia of the brainstem, malformations of the cerebellum, or other malformations that disturb the posterior fossa. The developmental consequences of these lesions are usually dire and to use the term *Dandy-Walker* in any form to describe these is not accurate embryologically and lowers the developmental expectations for true Dandy-Walker patients (Fig. 138.7).

PROCESS OUTGROWTH AND SYNAPSE FORMATION

Corpus Callosum

Callosal formation begins early in human development; the first axons crossing from one developing hemisphere to the other side are apparent at 6 weeks' gestation. By 11 to 12 weeks, there is an identifiable corpus callosum, and by 18 to 20 weeks, all of the structures of the corpus callosum are present (rostrum, body, splenium). Errant formation of this structure can result in complete agenesis, so-called partial agenesis or dysgenesis. The corpus callosum continues to form and differences in appearance may be seen through adolescence owing to myelination and pruning of crossing fibers.

The outcome depends on the genetic disorder, and outcome data is heavily biased toward poor outcomes. There is an ascertainment bias in many brain developmental disorders, but perhaps none more than in callosal disorders. Most patients with callosal agenesis/dysgenesis have neuroimaging because they have presented to a neurologist owing to developmental or neurologic issues. Asymptomatic people with callosal agenesis or dysgenesis are therefore not recognized. However, with commonplace fetal imaging, it is possible that more accurate data regarding outcomes in these disorders will be obtained. In fact, in a French cohort of 20 patients with agenesis or dysgenesis of the corpus callosum identified in utero (without prejudice), 80% have had normal outcomes up to 10 years later.

Multiple etiologies of agenesis/dysgenesis of the corpus callosum have been described and the potential etiologies are legion. For the clinician, the division into accompanying other brain malformations, isolated, and symptomatic seems the most useful. Examples of accompanying other brain malformations include Walker-Warburg and other muscle-eye-brain disorders, ciliopathies (see posterior fossa malformations), X-linked lissencephaly with ambiguous genitalia (*ARX* pathogenic variants), and Aicardi syndrome.

Aicardi syndrome occurs mostly in females (in XXY males), is accompanied by other brain anomalies (polymicrogyria, intracranial cysts, nodular heterotopia), and is defined by chorioretinal lacunae; the genetic basis of this disorder is unknown. The prognosis is poor and epilepsy is nearly a certainty.

It is important for the clinician to recognize that structural brain disease can result from metabolic disorders. Nonketotic hyperglycinemia may result in agenesis/dysgenesis of the corpus callosum. With the structural brain disease and lack of acidosis, the neurologist and neonatologist may easily assume that the seizures, hypotonia, and depressed mental status at birth are the result of the brain malformation. Similarly, pyruvate dehydrogenase complex deficiency may result in callosal agenesis/dysgenesis with or without lactic acidosis.

An important review of the genetics of callosal dysgenesis was published as an editorial by Dobyns and nicely catalogs observations with and without other CNS malformations associated with duplications, deletions, trisomies, and point pathogenic variants (recessive, X-linked and dominant). A reasonable evaluation of a patient symptomatic from a callosal dysgenesis would include an ophthalmologic exam if female to rule out Aicardi syndrome, metabolic studies to include cerebrospinal fluid glycine to serum glycine ratios, serum amino acids, urine organic acids, chromosomal microarray, and, if these are negative, consideration for whole exome sequencing.

Fetal recognition of isolated agenesis of the corpus callosum may carry a different prognosis as discussed earlier. Eighty percent of the fetuses so identified will be normal in follow-up. When evaluating the fetus with a corpus callosum malformation, it is important to recognize that Aicardi syndrome, with its poor prognosis, needs to be considered as a possibility for females.

Normal Synapse Formation

Even as neurons are arriving in the cortical plate, important neural outgrowths and synapses are forming. The process by which neurons sprout new extensions (neurites) that grow impressive distances to make precise synaptic connections is remarkable and has been well studied, although it is still being elucidated. During development, many more synapses are made than are needed; these subsequently are pruned to improve precision of synaptic connections. Such pruning occurs while other synapses are strengthened. Pruning may be a phenomenon peculiar to the developing nervous system, but synapse strengthening probably continues throughout life.

Most early neurites will form axons. The distance and the terrain that a forming axon must negotiate to reach its target is often formidable; yet, this process occurs with little error. Neurites consist of a long shaft of dynamic cytoskeletal elements that terminate in a growth cone, a highly motile structure capable of responding to chemical cues.

The nature of the chemical cues that guide growth cones and, thus, developing axons are threefold: adhesive, chemoattractive, and chemorepulsive. Adhesive molecules, such as those in the NCAM family, line projection pathways; integrin receptors on growth cones and neurites link the internal cytoskeleton of these structures with the extracellular adhesive molecules. These adhesive molecules provide a substrate on which the motile growth cone and neurite can respond to the chemical cues that determine the final synaptic target.

Diffusible cues appear to provide a trophic influence on developing axons through a chemoaffinity mechanism. One hypothesis is that gradients of chemotactic substances, emitted at the targets for synapse formation, interact with receptors on the growth cone that steer the growth cone toward the target.

Although it appears not to play a role in the early stages of synapse formation, synaptic activity is critical for subsequent remodeling. Pathways apparently are overrepresented often in early postnatal life, and "exuberant" projections of axons must be appropriately pruned. This occurs in a use-dependent fashion such that pathways used for neural activity are retained and those not used are eliminated. The classic studies of Hubel and Wiesel have demonstrated that this process is critical in the formation of the proper synaptic connections of the visual cortex. In their studies, the eyelid of one kitten eye was closed temporarily, and the eye deprived of light was underrepresented, whereas the eye that remained open was overrepresented in the visual cortex. This phenomenon is noted in children who have significant amblyopia (so-called lazy eye). If this amblyopia is not recognized during a critical period of synapse remodeling, these children can be cortically blind in the affected eye.

Throughout life, significant synaptic plasticity persists. Memory is believed to result from a strengthening of heavily used synapses, a phenomenon known as *long-term potentiation*. Considering the lessons learned about the role neuronal activity plays in the remodeling of connectivity in sensory systems, one wonders whether early life experiences, such as seizures, could also alter local circuit remodeling for the recurrent axon collaterals of hippocampal pyramidal cells. Hence, during hippocampal development, if repeated seizures occur, the synchronous discharging of pyramidal cells might prevent axonal remodeling that normally takes place, and an excess in axonal branching present in early life could be maintained into adulthood. In turn, this consolidation could result in an imbalance between recurrent excitation and inhibition and lead to the production of a chronic epileptic focus in hippocampus.

Disorders of Process Outgrowth

The disorders of process outgrowth probably are poorly recognized, given the current limitations of neuroimaging. Many children with cerebral palsy and normal neuroimaging scans likely have disorders involving dendritic branching and axonal growth. While there are likely many synapse disorders, a number have been well characterized.

Down syndrome (trisomy 21) includes a static encephalopathy characterized by mental retardation and hypotonia. The major neuropathologic changes in Down syndrome are a reduction in both the dendritic spines and the number of synapses.

Rett syndrome is a progressive disorder that affects girls and is due to a loss of function of *MECP2*. After a normal gestation, normal birth, and normal first 6 months of development, regression in intellect and motor function is seen. Girls affected with this disorder develop a gait and a truncal apraxia, loss of purposeful hand movements, stereotypic hand movements, progressive spasticity, autism-like social withdrawal, and intellectual disability. Accompanying this decline is a deceleration in head growth, which occurs during a time that brain development mainly involves glial proliferation and neuronal process outgrowth. Although patients typically have normal head sizes at birth, they become microcephalic during the time of their decline in function.

Pathologic examinations of the brains of patients with Rett syndrome support a disturbance in neuronal process outgrowth. The size of individual neurons is reduced, which is accompanied by an increase in packing density in the cerebral cortex, thalami, and basal ganglia. Abnormal dendritic branching has been noted in affected brain; this is especially prominent in layers III and V neurons of the frontal, motor, and temporal cortices. Because dendritic branching is believed to occur in response to axonal innervation, an examination of Rett syndrome brains for axonal aberrations revealed significantly lower numbers of axons entering cortex as compared to normal.

Fragile X syndrome is the most common nonchromosomal, genetic form of mental retardation seen in boys and men. The disorder results from the disturbance of the *FMR1* gene on the long arm of the X chromosome by a triplicate repeat. The brain in this disorder appears normal, but, on microscopic examination, dendritic spine abnormalities are apparent.

Autistic spectrum disorders may turn out to be disorders of synapses. Male patients with autism may have an abnormal acceleration in head growth before age of 2. Neuroligins and other synapse-specific targeting proteins implicated in autism are on the X chromosome, perhaps explaining, in part, the increased incidence of autism in boys.

CONCLUSIONS

Exciting, new genetic and molecular understanding of nervous system development and disturbances in that development have led to this attempt to give the clinician the framework to understand malformations of the human CNS and to evaluate patients afflicted by these disorders. Obtaining an etiology in such situations is of value to the patient, the family, and potentially to society. With new technologies such as exome sequencing, ribonucleic acid sequencing, and genomic sequencing, the potential for obtaining an etiology is vastly enhanced.

Inherited Metabolic Diseases 139

Marc C. Patterson

KEY POINTS

1. Inherited metabolic diseases are individually rare but collectively frequent; every neurologist will encounter such patients.
2. Small molecule disorders (amino and organic acid disorders, urea cycle disorders, oxidative phosphorylation defects) typically present most severely in neonates or in older children and adults under conditions of metabolic stress, such as intercurrent illness, pregnancy, or gastrointestinal hemorrhage.
3. Large molecule disorders (lysosomal disorders, peroxisomal disorders, glycogen storage diseases) have more insidious progression, with progressive weakness, or progressive neuro degeneration, accompanied by cognitive impairment, seizures, movement disorders, and sensory impairments.
4. The possibility of an inherited metabolic disorder should be considered in any patient with multisystem manifestations not readily explained by another mechanism (vascular, infectious, nutritional, or immunologic), although the possibility of dual diagnosis should also be considered.
5. Most patients with inherited metabolic disease have recognizable phenotypes, which can guide focused testing.
6. Next generation sequencing has revolutionized the diagnosis of inherited metabolic diseases, but owing to the difficulty in interpreting variants of undetermined significance, biochemical confirmation is always desirable, where feasible.
7. Specific therapies are available, or in prospect, for an increasing number of inherited metabolic diseases. Patients deserve an accurate and timely diagnosis to ensure implementation of specific therapy and to permit timely genetic counseling.

INTRODUCTION

There are hundreds of inherited metabolic diseases (IMDs), each individually rare, but collectively sufficiently common to constitute a significant public health burden. Most severe IMDs involve the nervous system either directly, or by producing neurologic dysfunction through intoxication with toxic substrates, energy deficiency (to which the brain is especially prone), deficiency of essential substrates or neurotransmitters, or combinations thereof. Although the complexity of these disorders defies easy classification, they may be conveniently divided into small and large molecule disorders for clinical purposes. The former group includes amino and organic acidopathies, and urea cycle disorders, among others. Most result from enzyme deficiencies that impair the body's ability to cope with substrate loads. In severe forms, they present in neonates exposed to normal substrates for the first time without their mother's metabolic machinery to compensate. Lesser degrees of impairment may present later and intermittently under conditions of unusual stress.

In contrast, large molecule disorders, which include the lysosomal, peroxisomal, and glycogen storage diseases, have a slowly but inexorably progressive course, paralleling the accumulation of macromolecules within cells. The most severe phenotypes exhibit specific patterns of neurodegeneration, reflecting the loci of storage and dysfunction in the nervous system. Thus, predominantly neuronal storage, as seen in the neuronal ceroid lipofuscinoses (NCLs) and neuroaxonal dystrophies, presents as poliodystrophies. Disorders in which white matter bears the major burden of disease are designated as leukodystrophies.

This chapter surveys some of the more prominent of these disorders but cannot be comprehensive. Indeed, the major text of inherited metabolic disease (*Metabolic and Molecular Bases of Inherited Disease*) was last published in print form in 2001, when its 4,600 pages had reached the limits of print publishing. The *Metabolic and Molecular Bases of Inherited Disease* is now only available as an electronic text Online Metabolic and Molecular Bases of Inherited Disease, and the interested reader is referred to it and the recommended reading lists in each of the following sections for more comprehensive data on disorders of interest. Other useful resources include several freely databases and applications that can be used at the bedside on a smartphone or tablet: Online Mendelian Inheritance in Man (OMIM) at https://www.ncbi.nlm.nih.gov/omim, GeneReviews at https://www.ncbi.nlm.nih.gov/books/NBK1116/, the Electronic Vademecum Metabolicum at http://www.vademetab.org/, and Treatable Intellectual Disability at http://www.treatable-id.org/ (treatable-id.net on portable devices).

SMALL MOLECULE DISORDERS

Glucose Transporter Type 1 Deficiency Syndrome

Clinical Syndrome

In 1991, De Vivo et al described two children with infantile seizures, delayed motor and behavioral development, acquired microcephaly, and ataxia. Lumbar puncture revealed low cerebrospinal fluid (CSF) glucose concentrations (hypoglycorrhachia) and low-normal to low CSF lactate concentrations.

Seizures begin in early infancy, and the seizure types vary with the age of the patient. In infancy, the dominant seizure types include behavioral arrest, pallor and cyanosis, eye deviation simulating opsoclonus, and apnea. The electroencephalogram (EEG) at this stage may be normal or show focal spikes in infancy and evolves to a generalized spike-wave pattern in childhood.

In childhood, the seizures typically include astatic seizures, atypical absence seizures, and generalized tonic-clonic seizures. The seizures are refractory to antiepileptic drugs but respond to a ketogenic diet. Other paroxysmal events often induced by exertion, including abnormal eye movements, ataxia, paralysis (with or without migraine), and dyskinesias, are frequent. Many patients exhibit static defects, of which intellectual disability, ataxia, dystonia, and spasticity are prominent.

Laboratory Data

Diagnosis requires awareness of the clinical manifestations and documentation of hypoglycorrhachia (CSF glucose <40 mg/dL or 2.2 mmol/L, in the absence of hypoglycemia). A low or low-normal CSF lactate concentration strengthens the presumptive diagnosis.

Molecular Genetics and Pathogenesis

D-Glucose is the obligate fuel for brain metabolism under virtually all circumstances. With fasting, the brain adapts to use ketone bodies (β-hydroxybutyrate and acetoacetate) in partial lieu of glucose. The transport of D-glucose across the blood-brain barrier and into brain cells is selectively mediated by glucose transporter 1 (GLUT1), a member of a multigene family of protein transporters that facilitate the diffusion of sugar molecules across tissue barriers. GLUT1 is encoded by *SLC2A1* on chromosome 1p34.1, and is present in high abundance in brain capillaries, astroglial cells, and erythrocyte membranes.

The molecular basis of the syndrome is GLUT1 haploinsufficiency; a few patients are hemizygous, but most are heterozygous with a variety of mutations. This syndrome is the first genetically determined abnormality of the blood-brain barrier; it may be familial and transmitted as an autosomal dominant trait.

Diagnosis

Lumbar puncture for measurement of glucose and lactate (with simultaneous serum assays of both) is critical in establishing the diagnosis. Confirmatory evidence is provided by sequencing of the *SLC2A1* gene; mutations are found in more than 90% of cases; severe phenotypes have been associated with microdeletions in the *SLC2A1* region.

Management

Standard treatment is the ketogenic diet, which controls the seizures, at least early in the course, but is less effective in improving cognition and behavior. More recently, anaplerotic therapy with triheptanoin has been studied, with evidence of benefit. Several trials of this agent were in progress in 2019. Antiepileptic drugs have been uniformly ineffective.

Hyperammonemia

Hyperammonemia has many genetic and acquired causes. The hepatic urea cycle is the major mammalian system for the detoxification of ammonia and defects have been described in all six urea cycle enzymes. The prevalence of these disorders is 1:35,000; two-thirds present after the newborn period. The mortality is 24% in neonates and 11% in older individuals. An additional pathway from arginine to citrulline generates the putative second messenger and neurotransmitter, nitric oxide, catalyzed by nitric oxide synthetase. The enzyme is found in many tissues, including brain. Animal studies suggest that derangement of this pathway, cerebral energy metabolism, amino acid and neurotransmitter pathways, mitochondrial permeability, signal transduction, and oxidative stress all contribute to the brain injury associated with exposure to high levels of ammonia.

Neonatal Hyperammonemia

Transient hyperammonemia is occasionally seen in otherwise well premature infants and rarely requires treatment. Hyperammonemia may reflect liver damage associated with birth asphyxia or congenital hepatic disease; the birth history usually establishes the diagnosis.

The ill neonate with hyperammonemia without other explanation often has an inborn error of metabolism that, directly or indirectly, affects the urea cycle. Marked hyperammonemia causes progressive lethargy, vomiting, poor feeding, apneic episodes, and seizures. These nonspecific symptoms occur in many disorders, such as sepsis, that can also precipitate hyperammonemia. The age at onset of these symptoms is a useful differential diagnostic point. Infants with hyperammonemia owing to urea cycle enzymopathies or organic acidurias typically are well until they have received 1 to 3 days of protein feeding. In contrast, infants with hyperammonemia secondary to impaired pyruvate metabolism are symptomatic within the first 24 hours. Pyruvate dehydrogenase and pyruvate carboxylase (type B) deficiencies feature lactic acidosis, and these diagnoses can be confirmed by an assay of enzyme activities in fibroblasts and/or direct sequencing of the relevant genes.

Organic acidurias (with the exception of maple syrup urine disease) lead to ketoacidosis, which distinguishes them from urea cycle enzymopathies. Severe deficiency of urea cycle enzymes, other than arginase, causes similar clinical syndromes. The affected child is well for the first 24 hours, but signs of hyperammonemia appear as protein feedings continue. Respiratory alkalosis with hyperventilation is classic, but not always present, and infants with sepsis or vomiting may have metabolic acidosis or alkalosis. Plasma amino acid and orotic acid assays help to distinguish different urea cycle defects (**Table 139.1**).

TABLE 139.1 Plasma Amino Acid and Urinary Orotic Acid Findings in Urea Cycle Defects

Enzymatic Deficiency	Citrulline	Argininosuccinic Acid	Orotic Acid	Arginine
Carbamyl phosphate synthetase (CPS)	0 to trace	0	↓	↓
Ornithine transcarbamylase (OTC)	0 to trace	0	↑↑	↓
Argininosuccinate synthetase (citrullinuria)	↑↑	0	↑	↓
Argininosuccinase (argininosuccinic aciduria)	↑	↑↓	nl	↓
Arginase	nl	0	↑	↑↑
Transient hyperammonemia of newborn	nl or slightly ↑	0	nl	nl

Abbreviations: ↑, increased; ↓, decreased; nl, normal.

Direct sequencing of urea cycle genes will make the diagnosis in more than 80% of cases; tissue enzyme analysis is required in the remainder. All of the urea cycle genes are autosomal recessive, except for ornithine carbamyl transferase deficiency, which is X-linked. Prenatal screening is available.

Prolonged exposure to high levels of ammonia damages the brain. Thus, acute hyperammonemic coma in the newborn is a medical emergency, and rapid reduction in ammonia levels is necessary. Peritoneal dialysis is more effective than exchange transfusion; hemodialysis may also be effective. Useful adjuncts include intravenous administration of sodium benzoate and sodium phenylbutyrate. A block in the urea cycle (other than at arginase) renders arginine an essential amino acid, which must be supplemented. Protein catabolism should be minimized by temporarily eliminating protein from the diet and by ensuring adequate caloric intake, principally as glucose. Long-term management depends on the specific enzyme defect.

Hyperammonemia in Older Children and Adults

Primary metabolic disease is much less likely a cause of hyperammonemia in an older child or adult than in neonates. Partial urea cycle defects (as seen in ornithine transcarbamylase heterozygotes—ie, women) may cause episodic hyperammonemia during periods of metabolic stress and should be considered, especially if there are affected relatives. Allopurinol loading, popular historically, has been supplanted by sequencing of urea cycle genes. Heterozygotes for ornithine transcarbamylase deficiency have impaired neuropsychological function compared to controls; impeccable metabolic control is critical in preserving neurologic function. The older child or adult with hyperammonemia usually has severe liver disease or drug-induced hyperammonemia.

Valproate-Associated Hyperammonemia

Valproate therapy is one of the most common causes of hyperammonemia in clinical neurologic practice. Malnourished patients with carnitine deficiency and those with unrecognized urea cycle and fatty acid oxidation defects seem to be at higher risk for this complication. This dose-related laboratory finding may occur without clinical symptoms. The pathogenesis is disputed but may result from inhibition of hepatic *N*-acetylglutamate synthase activity by valproyl-coenzyme A (CoA). It is unclear whether patients become symptomatic from the increased ammonia under these circumstances.

L-Carnitine supplementation can prevent the development of hyperammonemia in animals and humans receiving valproate; the clinical significance of this reduction is unclear. Some authors routinely supplement L-carnitine in patients with reduced serum carnitine levels. In severe acute valproate hepatotoxicity with hyperammonemia, a disorder with high mortality, intravenous L-carnitine has been shown to improve survival compared to oral therapy with the same agent.

Disorders of Amino Acid Metabolism

Twenty-one amino acids are required for normal human metabolism; the 21st, selenocysteine, has a unique metabolic role, differing from the other amino acids. Amino acids are the basic elements in the construction of proteins and enzymes as well as other compounds including hormones, neurotransmitters, and nucleotides.

Nine amino acids cannot be synthesized endogenously and are thus designated as "essential" (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine). The nonessential amino acids are mostly synthesized from glucose, whereas tyrosine is a product of the metabolism of phenylalanine, and cysteine is a product of the metabolism of methionine.

Mass screening for disorders of amino acid metabolism has resulted in early biochemical diagnosis of phenylketonuria (PKU) and other aminoacidopathies. In one screening program in New South Wales, Australia, the incidence of PKU was 1:10,000 live births per year; the incidence of defects of amino acid transport was about 2:10,000 live births per year; and the combined incidence of all other aminoacidopathies was less than 8:100,000 live births per year. Although these conditions are rare, they are important because neurologic damage is potentially preventable with early treatment and because they provide information about the development and functions of the brain. PKU is described in some detail as a model for this family of disorders.

Phenylketonuria

Phenylalanine hydroxylase deficiency is an autosomal recessive inborn error of metabolism manifested by impaired hepatic hydroxylation of phenylalanine to tyrosine, leading to elevated levels of phenylalanine in the blood and urine. Untreated, the disorder causes a clinical picture highlighted by intellectual disability, seizures, and imperfect hair pigmentation.

The disease has been found in all parts of the world. The incidence varies around the world, being highest in the Turkish population at approximately 1:2,500 to approximately 1:10,000 in Northern European and East Asian populations.

Pathogenesis and Pathology

The hydroxylation of phenylalanine to tyrosine is an irreversible and complex reaction that requires phenylalanine hydroxylase and five other enzymes, in addition to several nonprotein components. Phenylalanine hydroxylase is normally found in liver, kidney, and pancreas, but not in brain or skin fibroblasts.

In classic PKU, enzyme activity is generally less than 5% of normal. More than 40% of PKU subjects and more than 80% of those with mild PKU are tetrahydrobiopterin (BH_4) responsive when challenged with 20 mg/kg BH_4.

In some 1% to 3% of subjects, hyperphenylalaninemia results from a deficiency of BH_4. The BH_4-deficient hyperphenylalaninemias comprise a genetically heterogeneous group of disorders caused by mutations in the genes encoding enzymes involved in the synthesis or regeneration of the coenzyme BH_4. Three genetic defects in the synthesis of BH_4 have been described. These involve guanosine triphosphate cyclohydrolase 1, 6-pyruvoyl-tetrahydropterin synthase, and sepiapterin reductase. In addition, there are two disorders in the regeneration of the aromatic amino acid–hydroxylating system: dihydropteridine reductase and pterin-4a-carbinolamine dehydratase. All these conditions lead to hyperphenylalaninemia associated with progressive neurologic deterioration, along with a variety of dyskinesias.

Children with classic PKU are born with only slightly elevated phenylalanine blood levels, but these rise rapidly on an unrestricted diet. Phenylalanine is converted to phenylpyruvic acid, phenylacetic acid, and phenylacetylglutamine, which impart a characteristic odor to the urine.

Brain changes are nonspecific and diffuse and involve both gray and white matter; they include interference with normal maturation of the brain, defective myelination, and diminished or absent pigmentation of the substantia nigra and locus ceruleus.

Symptoms and Signs

PKU exhibits a wide range of clinical and biochemical severity. In the classic form, untreated infants appear normal at birth. Vomiting and irritability in the first few months is followed by cognitive delay; ultimate intellectual disability may be severe. Seizures, including epileptic spasms, usually present in the first 18 months.

Untreated children are fairer, with lighter irides than unaffected sibs, and may have eczema and a peculiar musty ("mousey") odor. Focal neurologic abnormalities are rare, but microcephaly, mild spastic paraparesis, and tremor may occur.

Magnetic resonance imaging (MRI) usually shows white matter signal hyperintensity on T2-weighted sequences, mainly in the posterior watershed regions.

Diagnosis

Most PKU patients are identified through newborn screening. If the diagnosis of a case of classic PKU is missed, the most likely reason is laboratory error, rather than insufficient protein intake or too early testing of the infant.

Mutation analysis facilitates carrier detection and the prenatal diagnosis of PKU in families with at least one previously affected child. Newborn screening programs have also detected conditions other than PKU with neonatal hyperphenylalaninemia. Patients with moderate and mild PKU and mild hyperphenylalaninemia, as these entities are termed, have phenylalanine levels that tend to be lower than those seen in classic PKU.

Management

All infants whose blood phenylalanine concentration is greater than 10 mg/dL (600 μM/L) and whose tyrosine concentration is low or normal (ie, 1-4 mg/dL) should be started on a low-phenylalanine diet immediately. Infants whose blood phenylalanine concentrations remain in the range of 6.6 to 10.0 mg/dL (400-600 μM/L) on an unrestricted diet are generally not treated, and on follow-up evaluations, children of this group have normal intelligence and a normal MRI.

Therapy for classic PKU is restriction of the dietary phenylalanine, using one of several low-phenylalanine formulas. Milk is added to the diet in amounts sufficient to maintain blood levels of the amino acid between 2 and 6 mg/dL (120-360 μM/L). Generally, patients tolerate this diet quite well, and within 1 to 2 weeks, the serum concentration of phenylalanine becomes normal.

Weekly serum phenylalanine determinations are essential to monitor dietary adherence for life. Strict dietary control should be maintained for life, and most centers strive to keep levels below 6 mg/dL (360 μM/L) in all patients with PKU. Dietary lapses are frequently accompanied by progressive white matter abnormalities on MRI. The addition of sapropterin (5-20 mg/kg/d), an orally active synthetic form of BH_4, permits a less restrictive diet for those patients who respond to a BH_4 challenge.

Phenylalaninemia caused by BH_4 deficiency requires diet, administration of BH_4 or a synthetic pterin, and replacement of neurotransmitter precursors (L-dopa/carbidopa and 5-hydroxytryptophan), whose synthesis is also impaired.

Early detection and dietary control of PKU has increased the number of homozygous PKU women achieving pregnancy. Maternal hyperphenylalaninemia causes intellectual disability, microcephaly, seizures, and congenital heart defects in affected children. During pregnancy, phenylalanine levels must be monitored as closely as during infancy because the fetus is exposed to even higher phenylalanine concentrations than the mother.

Prognosis

When a child with classic PKU is maintained on a low-phenylalanine diet, seizures disappear and the EEG normalizes. Abnormally blond hair regains natural color, and head growth resumes.

Cognitive effects are less clear cut. In most studies, some deficit in intellectual development has been found, even in infants who had been diagnosed and treated as neonates. This could be a consequence of prenatal brain damage induced by high phenylalanine levels in the fetus.

Although the measured IQ is normal in most, deficits have been noted in executive functioning, attention, verbal memory, verbal fluency, and expressive naming. There is no threshold below which phenylalanine has no effect on cognition. Neurologic deterioration during adult life is generally the consequence of dietary lapses.

Other Amino Acid Disorders

Several other aminoacidopathies have distinguishing features that enable the clinician to suspect the diagnosis. Maple syrup urine disease, a disorder of branched chain amino acid metabolism, produces a characteristic odor (detectable in cerumen as well as urine) and classically presents in the first week of life with acute encephalopathy and opisthotonic posturing. Isoleucine, leucine, and valine are present in excess in the urine. Emergent diagnosis and management is necessary to preserve life and neurologic function; a few patients are thiamine responsive. Later onset forms may also occur.

Homocystinuria is manifest as tall stature, dislocated lenses, and varying degrees of intellectual impairment; a subgroup of patients responds to therapy with cobalamin. Thromboembolic episodes may begin in infancy. Disorders of sulfur amino acids are summarized in **Table 139.2**.

Hartnup disease is a disorder of renal tubular transport of tryptophan and other neutral amino acids; it causes intermittent ataxia with a pellagra-like rash. The disorders of amino acid transport are summarized in **Table 139.3**.

Organic Acidurias

Progress in diagnostic techniques in the 1950s enabled the identification of a family of disorders of distal steps in intermediary metabolism marked by the accumulation of nonamino organic acids, which are preferentially excreted in the urine and are not detectable in bodily fluids by older methods. These compounds are mono-, di-, and tricarboxylic acids derived from the breakdown of amino acids through the intramitochondrial degradation of CoA-activated carbonic acids. They are separated from the amino acid disorders only because of the analytical methods employed in their diagnosis, not because of any fundamental biologic difference. The classic organic acidurias have a number of common clinical features, including precipitation of acute encephalopathy, acidosis, and hyperammonemia, and other multisystem manifestations, by an excess substrate load or metabolic stress in the form of fever or other illness that leads to a hypercatabolic state. Profound brain and systemic injury follows unless rapid and effective intervention is undertaken. This usually involves substrate restriction, suppression of aberrant pathways by providing alternate energy sources, and removal of offending metabolites by dialysis, hemofiltration, or by activating alternate pathways. The classical organic acidurias include propionic aciduria, methylmalonic aciduria, and isovaleric aciduria.

TABLE 139.2 Disorders of Sulfur Amino Acids

Disorder	Enzyme Deficiency	Neurologic Picture
Homocystinuria	Cystathionine-β-synthase	Multiple thromboembolic episodes starting in first year of life, mental retardation, ectopia lentis
Homocystinuria and mild homocysteinemia	$N^{5,10}$-methylenetetrahydrofolate reductase	Seizures, microcephaly, spastic paraparesis, ataxia
Cystathioninuria	γ-Cystathionase	Asymptomatic
Homocystinuria With Megaloblastic Anemia		
Cbl E	Methionine synthase reductase	Severe developmental delay, lethargy, staring spells, hypotonia
Cbl G	Methionine synthase	Failure to thrive, mental retardation, cerebral atrophy
Cbl C	Synthesis of methyl and adenosyl cobalamin	Marfanoid habitus, mental retardation, acute psychosis, subacute spinal cord degeneration
Cbl D	Synthesis of methyl and adenosyl cobalamin	Acute psychosis, mental retardation, subacute spinal cord degeneration, Marfanoid habitus
Cbl F	Cobalamin lysosomal release	Developmental delay, sudden death in infancy
Sulfite oxidase deficiency	Sulfite oxidase	Seizures starting in neonatal period, profound mental retardation, subluxation of lens
Molybdenum cofactor deficiency	Molybdenum cofactor deficiency	As for sulfite oxidase deficiency

Abbreviation: Cbl, cobalamin.

Propionic aciduria is associated with a poor long-term neurologic outcome, as assessed by cognitive measures and the presence of basal ganglia lesions; isovaleric aciduria is typically associated with an excellent outcome; and methylmalonic aciduria is associated with intermediate impairment of neurologic function. Early diagnosis and tight metabolic control are necessary, but not always sufficient, to achieve the best outcome in these disorders.

Most of these diseases result from deficient activity of enzymes or their cofactors and present as neonatal encephalopathies in their most severe forms; less profound defects may present intermittently in older children. Slowly progressive disorders with predominant or exclusive neurologic manifestations are designated as cerebral organic acidopathies and include glutaric aciduria type 1, L-2-hydroxyglutaric aciduria, D-2-hydroxyglutaric aciduria (D-2-HGA), succinic semialdehyde dehydrogenase deficiency, and Canavan disease.

Glutaric aciduria type 1 results from glutaryl CoA dehydrogenase deficiency and manifests as macrocephaly, hypotonia, and mild motor delay; affected children can decompensate suddenly in the face of metabolic stress and exhibit a hyperkinetic movement disorder that is refractory to most therapy. The MRI shows enlarged extra-axial spaces over the frontal and temporal convexities, with widened Sylvian fissures. Signal hyperintensity and eventual necrosis occur in the striatum in untreated cases and correlate with the presence of a hyperkinetic movement disorder. Glutaric acid and 3-methyl glutaric acid are excreted in excess in the urine, as is glutarylcarnitine. Carnitine supplementation is of proven benefit in preventing neurologic progression but must be introduced early if permanent basal ganglia injury is to be prevented.

L-2-hydroxyglutaric aciduria is associated with mutations in the L2HGDH gene and presents with progressive ataxia and intellectual disability in children; adult onset with similar, more slowly progressive symptoms, also occurs on occasion. The MRI shows a characteristic pattern that involves the basal ganglia and dentate nuclei, as well as the subcortical, but not cerebellar, white matter. Patients with this disorder have an increased risk

TABLE 139.3 Defects in Amino Acid Transport

Transport System	Condition	Biochemical Features	Clinical Features
Basic amino acids	Cystinuria (three types)	Impaired renal clearance, defective intestinal transport of lysine, arginine, ornithine, and cystine	Renal stones, no neurologic disease
	Lowe syndrome	Impaired intestinal transport of lysine and arginine, impaired tubular transport of lysine	Severe mental retardation, congenital glaucoma, cataracts, myopathy
Acidic amino acids	Dicarboxylic aminoaciduria	Increased excretion of glutamic, aspartic acids	Severe mental retardation, glaucoma, cataracts, myopathy, sex-linked transmission
Neutral amino acids	Hartnup disease	Defective intestinal and renal tubular transport of tryptophan and other neutral amino acids	Intermittent cerebellar ataxia, photosensitive rash
Proline, hydroxyproline, glycine	Iminoglycinuria	Impaired tubular transport of proline, hydroxyproline, and glycine	Harmless variant
β-Amino acids	None known	Excretion of β-aminoisobutyric acid and taurine in β-alaninemia is increased due to competition at the tubular level	Harmless variant

of primary brain tumors attributed to the putative "oncometabolite" 2-hydroxyglutarate.

D-2-hydroxyglutaric aciduria is genetically and clinically heterogeneous. Some patients who excrete D-hydroxyglutaric acid in the urine are asymptomatic; others exhibit facial dysmorphism, seizures, hypotonia, and developmental delay. About half of the patients have recessive mutations in D2HGDH, designated type 1 D-2-HGA. The remainder, designated type 2 D-2-HGA, harbor dominant mutations in IDH2, a gene which is mutated in some cases of acute myeloid leukemia and gliomas. A few patients have been described with combined D- and L-2-hydroxyglutaric aciduria resulting from mutations in the SLC25A1 gene. The phenotype is severe, with hypotonia, delay, and intractable seizures; it is important to recognize, as it may respond to therapy with citrate.

Succinic semialdehyde dehydrogenase deficiency is a disorder of γ-aminobutyric acid metabolism that results from mutations in ALDH5A1 and presents with hypotonia, developmental delay, and ataxia. Fewer than 200 patients had been described by the time of the most recent review, in 2017. Epilepsy, which may be difficult to control, occurs in more than half of affected children, along with movement disorders and behavioral disturbances. The MRI may show hyperintensities in the basal ganglia, specifically the globus pallidus, and less frequently in the dentate nuclei, brainstem, and subcortical white matter. The 4-hydroxy butyric acid is increased in urine and CSF and may be detected by magnetic resonance spectroscopy (MRS). Treatment is symptomatic; vigabatrin (50 mg/kg/d; 500-1,500 mg twice daily), which inhibits the production of succinic semialdehyde, is a logical choice as an antiepileptic drug but is not always effective. Valproate (10-60 mg/kg/d) is relatively contraindicated but can be cautiously employed if seizures are refractory to other agents. A class IV trial of taurine showed no evidence of clinically meaningful benefit.

Canavan disease is a spongiform leukodystrophy in which deficient activity of aspartoacylase leads to accumulation of *N*-acetyl aspartic acid (NAA) in bodily fluids and the brain. It is commonly manifest as hypotonia and progressive macrocephaly in infants followed by loss of milestones, spasticity, seizures, and premature death. The MRI shows diffuse white matter hyperintensity, and MRS demonstrates marked elevation of NAA. Attenuated forms of the illness may lack diffuse white matter involvement but show only hyperintense signal in the basal ganglia. The diagnosis is made by demonstrating defective aspartoacylase activity in leucocytes and corresponding mutations in the ASPA gene. Antenatal diagnosis is possible using gene sequencing. Gene therapy using an adeno-associated dependoparvovirus A, serotype 2 vector has shown reduced NAA levels and evidence of clinical stabilization in an open-label study in humans with Canavan disease. The purification of aspartoacylase has led to the identification of potential inhibitors of this enzyme as a novel treatment strategy, and one murine study has shown that knocking down the activity of the gene (*N*-acetyltransferase 8-like [NAT8L]) encoding enzyme responsible for the synthesis of NAA (NAT8L) using a short hairpin inhibitory RNA suppresses the development of spongiform leukoencephalopathy in this model. Other studies have shown that knocking out NAT8L produces neurologic abnormalities in mice, suggesting that complete absence of NAA is detrimental. Studies in two mouse models of Canavan disease have demonstrated that correction of oligodendrocytes alone reverts established disease.

Disorders of Purine and Pyrimidine Metabolism

Introduction

Purines and pyrimidines are heterocyclic compounds that participate in nucleotide synthesis, generation of energy compounds (ie, adenosine diphosphate and adenosine triphosphate [ATP]), and in signaling pathways (eg, cyclic adenosine monophosphate). Several disorders of purine and pyrimidine metabolism have been recognized (Table 139.4). Findings include anemia, immunodeficiency, hypo- or hyperuricemia (with nephrolithiasis and renal failure in severe cases), and a variety of neurologic phenotypes. The latter range through sensorineural hearing loss, developmental delays, intellectual disability, autism, seizures, and movement disorders. The archetype and most frequently recognized of these disorders is the Lesch-Nyhan syndrome, described in more detail in the following paragraphs.

Lesch-Nyhan Syndrome

In 1964, Lesch and Nyhan described two brothers with hyperuricemia, intellectual disability, choreoathetosis, and self-destructive biting of the lips and fingers. Most cases are seen in males, but at least one symptomatic female with skewed X-inactivation has been described. The trait is X-linked recessive. The basic defect is the lack of hypoxanthine-guanine phosphoribosyltransferase. The enzyme deficiency increases the rate of purine biosynthesis, and uric acid reaches high levels in blood, urine, and CSF. Urate is deposited in the kidneys and joints and may result in nephropathy and gout.

The neurologic manifestations include severe intellectual disability, spasticity, and choreoathetosis that start in the first year. The characteristic self-mutilating behavior appears in the second year. Death is usually caused by renal failure and may occur in the second or third decade of life. Sudden death may occur at any time because of acute respiratory failure, often related to the motor disorder. Milder variants are recognized, in which self-mutilation may be absent and manifestations may be restricted to cognitive impairment with mild motor symptoms, or progressive spastic paraparesis. The pathogenesis of the cerebral symptoms is not known, but these symptoms are not prevented by the administration of allopurinol.

Diagnosis depends on recognition of the clinical manifestations and may be made precisely by biochemical assay of the enzyme in erythrocyte hemolysates or cultured fibroblasts. The DNA analysis confirms the diagnosis and may be used for prenatal diagnosis and carrier detection; mutations can be detected in most affected individuals. More than 400 mutations have been described.

Gout is treated effectively with allopurinol, but the neurologic disorder is daunting. Restraints may be needed to prevent affected children from damaging themselves or others; dental extraction is often required to prevent facial mutilation. Diazepam (1-2.5 mg by mouth three to 4 times daily), carbamazepine (10-35 mg/kg/d), gabapentin (10-40 mg/kg/d), or botulinum toxin are sometimes helpful, and some patients may respond to *S*-adenosylmethionine (SAM), but physical restraint is often required in classic cases. Deep brain stimulation surgery, targeted to the globus pallidus, has improved or abolished self-mutilation in some cases. Neither enzyme replacement nor gene therapy is available for Lesch-Nyhan syndrome.

TABLE 139.4 Disorders of Purine and Pyrimidine Metabolism

Enzyme	Anemia	ID	Uric Acid	MR	SNHL	Seizures	Ataxia	MD	Other
cNT	+	+	–	+		+	+	+	Symptoms improve with uridine

UP	–	–	0	+	–	+	–	+	

Abbreviations: +, present (or increased for uric acid); –, absent (or decreased for uric acid); 0, phosphoribosyl pyrophosphate; ADA, adenosine deaminase deficiency; ADSL, adenylosuccinate lyase deficiency; AMPD1, muscle adenosine monophosphate deaminase deficiency; APRT, adenosine phosphoribosyltransferase deficiency; CK, creatine kinase; DPYD, dihydropyrimidine dehydrogenase deficiency; DPYS, dihydropyrimidinase deficiency; HPRT, hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome); ID, immunodeficiency; cNT, cytosolic 5′-nucleotidase superactivity (nucleotide depletion syndrome); MD, movement disorder; MR, developmental delay, mental retardation; NP, nucleoside phosphorylase deficiency; PRPS, phosphoribosyl pyrophosphate synthetase superactivity; SNHL, sensorineural hearing loss; UMPH1, uridine monophosphate hydrolase (pyrimidine 5′-nucleotidase) deficiency; UMPS, uridine monophosphate synthase deficiency (hereditary orotic aciduria); UP, ureidopropionase deficiency; XDH, xanthine dehydrogenase (xanthine oxidase) deficiency (xanthinuria; secondary impairment in molybdenum cofactor deficiency).

Other Purine Disorders

Neurologic abnormalities are also seen in patients who are without other enzymes of purine-nucleoside metabolism. **Adenosine-deaminase deficiency** causes severe, combined immunodeficiency in infants; some patients have extrapyramidal or pyramidal signs and psychomotor development and may be retarded. Partial exchange transfusion may be clinically beneficial. Also, a few patients lacking **purine-nucleoside phosphorylase** with impaired cellular immunity have shown a form of spastic paraparesis in childhood. 5′-Nucleotidase superactivity produces a complex phenotype with all of the features of purine and pyrimidine disorders; it responds to oral uridine therapy. These patients may have autistic features that may also be prominent in **phosphoribosyl pyrophosphate synthetase**, **adenylosuccinate lyase**, and **dihydropyrimidine dehydrogenase** deficiencies.

Porphyrias

The porphyrias are a family of disorders in which the synthesis of heme, and its precursors, is impaired. They are traditionally divided into hepatic and erythropoietic subgroups according to the major sites of gene expression. **Acute intermittent porphyria** (AIP) is the most frequent of these disorders and the most likely to present to a neurologist.

The AIP is an autosomal dominant disorder with low penetrance caused by deficiency of hydroxymethylbilane synthase (also known as *porphobilinogen deaminase*), most frequently observed in Sweden and South Africa, which typically presents as an acute encephalopathy with pronounced behavioral changes (including frank psychosis) that may be accompanied by seizures, autonomic neuropathy causing abdominal pain, tachycardia and hypertension, or a painful motor neuropathy that may progress to quadriplegia with respiratory failure in severe cases. Patients may have hyponatremia as a consequence of inappropriate antidiuretic hormone secretion. Decompensation may be provoked by fasting or by exposure to alcohol or any one of a number of drugs that interact with this pathway, including older anesthetic agents, barbiturates, and oral contraceptives; pregnancy may also precipitate an attack. Drugs appear to precipitate attacks of AIP by inducing δ-aminolevulinic acid synthase, thereby leading to hepatic heme depletion, or by inhibiting the P450 cytochrome system. Understanding these mechanisms facilitates prediction of the likely toxicity of drugs in affected individuals.

The diagnosis of AIP requires timely assay of urine porphobilinogen, with subsequent confirmation by sequencing of the hydroxymethylbilane synthase gene. Acute management, which must not be delayed for definitive diagnosis, requires the removal of precipitants, careful attention to fluid and electrolyte balance, the administration of intravenous Panhematin or heme arginate to shut down the synthetic pathway, appropriate analgesia with agents such as gabapentin (10-40 mg/kg/d), and management of seizures with safe agents such a benzodiazepines that do not exacerbate the metabolic block.

A number of atypical presentations have been reported in AIP, including posterior reversible encephalopathy syndrome, acute cortical blindness, and progressive muscular atrophy. Long-term management hinges on education of the patients and

their medical providers to recognize and avoid situations and agents that provoke decompensation. One study of two patients found that weekly administration of intravenous heme was associated with marked reduction in acute attacks and reduction in health care costs. In rare cases, liver transplantation may be indicated to manage hepatic failure or recurrent attacks when conservative management is ineffective; AIP may recur after successful transplantation if the donor has unrecognized disease.

Acute variegate porphyria, a dominant disorder associated with decreased activity of the mitochondrial enzyme protoporphyrinogen oxidase, can present in a clinically indistinguishable fashion from AIP because the typical blistering rash may be absent in as many as half of affected individuals in acute crises. It is managed in the same fashion as AIP.

Disorders of Metal Metabolism

Several inherited neurologic diseases are associated with abnormal handling of metals in the brain. These may be conveniently divided into disorders of copper and iron metabolism.

Disorders of Copper Metabolism

Wilson Disease

Kinnier Wilson described his eponymous disease in 1912 as hepatolenticular degeneration, a disorder characterized by progressive dystonia, tremor, and psychiatric disturbances, usually beginning in adolescence, and accompanied by cirrhosis. A decade earlier, Kayser and Fleischer had reported the brown corneal rings now known to represent the accumulation of copper in Descemet membrane. These have proven to be an excellent gauge of excess copper stores, which regress in the face of effective copper removal, only to reappear if treatment is discontinued.

Wilson disease is caused by mutations in the transporter, encoded by the ATP7B gene that transports copper from hepatocytes to the bile and blood; its dysfunction leads to accumulation of copper in the liver, where it provokes fibrosis and eventually cirrhosis. When this store is exhausted, copper begins to deposit in the lenticular nuclei, causing extrapyramidal dysfunction, and if untreated destruction of the nuclei.

Neurologic presentations are rare in the first decade of life; Wilson disease is more likely to present in young children with acute or chronic liver failure, hemolytic anemia, or renal tubular dysfunction, reflecting the tissues in which copper is toxic. Affected adolescents have a typical appearance, in which the upper lip is drawn back to expose the teeth, accompanied by a wing-beating tremor and dystonic posturing. Spasticity, dysphagia, and dysarthria are commonly seen, and Parkinsonian features are most prominent in some cases. Psychiatric manifestations are frequent and may dominate the clinical picture.

Laboratory tests may show elevated transaminases; low serum uric acid; and elevated urine copper, amino acids, and urate secondary to tubular dysfunction. Serum copper and ceruloplasmin are low. Apart from the demonstration of two mutations in trans in the ATP7B gene, no single test is diagnostic for Wilson disease. A diagnostic scoring system has been developed to assist the clinician; this includes presence or absence of Kayser-Fleischer rings or neurologic symptoms, serum ceruloplasmin, liver copper content, urinary copper excretion, and mutation analysis of the ATP7B gene.

Penicillamine (600-3,000 mg daily for adults; 20 mg/kg/d in children, rounded off to the nearest 250 mg, given in two or three divided doses) is the traditional chelating agent used in Wilson disease, but its adverse effect profile has led to the employment of zinc (which impairs copper absorption) (150 mg elemental zinc per day for adults; for children <50 kg in body weight, 75 mg/d, administered in three divided doses, 30 min before meals) and trientine (which increases urinary copper excretion) (900-2,700 mg/d in two or three divided doses, with 900-1,500 mg/d used for maintenance therapy; in children, the weight-based dose is not established, but the dose generally used is 20 mg/kg/d rounded off to the nearest 250 mg, given in two or three divided doses) as preferred treatments today. Vitamin E may have a role as an antioxidant, but no dosage regimen has been widely accepted. If copper stores can be removed before permanent tissue damage has occurred, the prognosis is excellent, provided that treatment is continued lifelong. Liver transplantation is an option in those with irreversible hepatic failure or who cannot tolerate other treatments.

Menkes Disease

In contrast to Wilson disease, the manifestations of Menkes disease reflect the effects of copper deficiency on the brain and other tissues. Menkes disease is caused by mutations in the X-linked ATP7A gene, which encodes the protein that facilitates transport of copper from the gut to the circulation. The resultant systemic deficiency of copper leads to dysfunction of multiple enzyme systems, including cytochrome c oxidase, lysyl oxidase, and dopamine β-hydroxylase. The disease manifests in boys in the first 2 months with developmental regression, hypotonia, seizures, twisted, sparse, fair hair (often absent through easy breakage), hypothermia, and hypoglycemia. They have a cherubic appearance secondary to abnormal collagen formation, which is also responsible for the bony anomalies (metaphyseal flaring) and dilatation of the urinary collecting system and blood vessels. The latter may rupture spontaneously, leading to intracranial hemorrhage, sometimes mistakenly attributed to child abuse. Without treatment, most boys die by 3 years, although survival into the fourth decade has been reported in one treated patient with a mild phenotype.

The diagnosis is suspected clinically and confirmed by ATP7A mutation analysis. Bypassing the impaired gut absorption by administering subcutaneous copper histidine has shown benefit in morbidity and mortality, provided that treatment is instituted before permanent damage has occurred. A combination of CSF-directed gene therapy and subcutaneous copper histidine has shown benefit in a mouse model of Menkes disease.

Females with ATP7A mutations can present when X-autosome translocation has occurred, or in theory, in cases of Turner syndrome. Their clinical manifestations resemble those in boys.

Two allelic variants have been recognized in patients with ATP7A mutations. The occipital horn syndrome manifests as calcification of the insertions of the trapezius muscles, associated with joint laxity, a dilated urinary collecting system, and tortuous blood vessels, with only mild, if any, cognitive impairment. A distal motor neuropathy resembling Charcot-Marie-Tooth syndrome has also been described in adult males; it lacks any other findings in common with Menkes disease.

Disorders of Iron Metabolism

A family of rare diseases, embraced by the acronym NBIA (neurodegeneration with brain accumulation) has been delineated in recent years. All feature varying combinations of basal ganglia dysfunction associated with neuropsychiatric symptoms. Ten of the 12 known subtypes are autosomal recessive disorders;

Beta-propeller protein-associated neurodegeneration (BPAN) is X-linked dominant, and neuroferritinopathy is autosomal dominant. The disorders have been classified into subgroups according to their proposed pathomechanisms: (1) abnormal CoA biosynthesis (pantothenate kinase–associated neurodegeneration [PKAN] and COASY protein-associated neurodegeneration), (2) abnormal lipid metabolism (PLA2G6-associated neurodegeneration [PLAN], mitochondrial-membrane protein-associated neurodegeneration, fatty acid hydroxylase-associated neurodegeneration, and leukoencephalopathy with dystonia and neuropathy), (3) autophagosome and lysosomal dysfunction (BPAN and Kufor-Rakeb syndrome), (4) iron homeostasis (neuroferritinopathy and aceruloplasminemia), and (5) those of uncertain mechanism (Woodhouse-Sakati syndrome and GTPBP2-associated NBIA). The core disorders in this family are PKAN (NBIA 1) (formerly known as *Hallervorden-Spatz disease*) and PLAN (NBIA 2).

PKAN, or NBIA 1, is a childhood-onset neurodegenerative disorder that most often presents in the first decade with intellectual delay and progressive gait and oromandibular dystonia; more subtle disturbances of cognitive function and gait may occur with later onset forms of the disease. Saccadic eye movement disorders including vertical supranuclear gaze palsy have been described. The classic phenotype also includes retinal pigmentation, acanthocytes, and deposition of iron in the globus pallidus. This causes signal hypointensity in the globus pallidus on MRI early in the course of the disease; with progression, a central area of hyperintensity appears in the medial globus pallidus, producing the "eye of the tiger" sign. Although highly suggestive of the diagnosis, the absence of this finding does not rule out the diagnosis of PKAN, which is established by sequencing of the PANK2 gene. Although there is no definitive therapy for PKAN, small studies suggest a stabilizing effect of iron chelation using deferiprone.

NBIA 2, PARK14 or PLAN, first recognized as infantile neuroaxonal dystrophy, is associated with mutations in PLA2G6, which encodes calcium-independent phospholipase A2. The key features are the combination of ataxia, truncal hypotonia, spasticity, nystagmus, and optic atrophy with peripheral neuropathy. The MRI shows cerebellar atrophy and iron deposition in the globus pallidus—without hyperintensity. Later onset forms may have a dystonia-Parkinson phenotype. Axonal spheroids are the pathologic hallmark of the disease, and their demonstration in biopsies was critical to the diagnosis before mutation analysis was available. Only symptomatic therapy is available.

Disorders Associated With Acanthocytosis

Acanthocytes are irregularly shaped red cells with spiny projections whose appearance reflects abnormal membrane structure. They are found in chorea-acanthocytosis, abetalipoproteinemia, hypobetalipoproteinemia, McLeod syndrome, PKAN (see above), and in Huntington disease-like 2, a triplet repeat disease affecting the gene encoding junctophilin-3, a protein involved in sarcoplasmic and plasma membranes.

Chorea-acanthocytosis is an autosomal recessive disorder in which patients experience the onset of a hyperkinetic movement disorder in early adulthood, which eventually evolves into parkinsonism. The movements are often drug resistant but may respond to deep brain stimulation targeted at the globus pallidus interna. A neuropsychiatric syndrome beginning with features of obsessive-compulsive disorder may evolve into dementia; some patients also have an axonal neuropathy and seizures. Death usually occurs within 15 years; there is no disease-modifying therapy. Patients have mutations in VPS13A, the human analog of the yeast vacuolar protein sorting 13 gene. The gene product, chorein, interacts with beta-adducin and beta-actin, membrane cytoskeletal proteins expressed at synapses and red cell membranes.

Two related disorders of lipid metabolism are also associated with acanthocytosis. **Abetalipoproteinemia (Bassen-Kornzweig syndrome)** is caused by mutations in the gene encoding the microsomal triglyceride transfer protein. This leads to severe diarrhea and almost complete absence of apoB-containing proteins in the blood, with very low levels of cholesterol (often less than 40 mg/dL) and other blood lipids. Fat-soluble vitamins are correspondingly low; perhaps the most significant is vitamin E, whose deficiency causes a spinocerebellar syndrome, progressive ophthalmoplegia, and pigmentary retinopathy. Vitamin K deficiency may cause serious bleeding. The presence of very low serum cholesterol and acanthocytes should suggest the diagnosis, which can be confirmed by mutation analysis. Treatment with vitamins E and K is effective if begun early. **Hypobetalipoproteinemia** results from mutations in the apoB gene itself; the phenotype is indistinguishable from abetalipoproteinemia; the treatment is the same.

McLeod syndrome is an X-linked disorder, originally recognized in asymptomatic individuals donating blood. They have abnormal expression of Kell blood group antigens secondary to mutations in the XK gene. A subgroup of people with this finding has a symptomatic neuromyopathy associated with elevated creatine kinase levels, hemolysis and involuntary movements; some also have seizures. The MRI shows caudate atrophy and increased signal in the putamen. Cardiomyopathy may occur and lead to premature death. The electromyography shows axonal degeneration, and muscle biopsy may show myopathy and denervation. Complex phenotypes likely result from contiguous gene syndromes; XK is adjacent to CYBB (causing X-linked chronic granulomatous disease), Duchenne muscular dystrophy, and RPGR (X-linked retinitis pigmentosa) on the X chromosome.

LARGE MOLECULE DISORDERS

Lysosomal and Associated Large Molecule Disorders

Lysosomal diseases are characterized by the accumulation of macromolecules within lysosomes because of genetically determined deficiency of a catabolic enzyme or related gene product. The stored materials comprise complex lipids, saccharides, or proteins, and the central nervous system (CNS) is usually affected. Both autosomal and X-linked inheritance occur. Carrier detection and prenatal diagnosis are available for most of these disorders. Specific treatment in the form of enzyme replacement therapy (ERT) for mucopolysaccharidosis (MPS) types I, II , VI, and VII and Gaucher, Fabry, Wolman, and Pompe diseases; substrate reduction therapy for Gaucher disease; and hemopoietic stem cell transplantation for several lysosomal storage diseases has now entered practice, albeit with varying evidence of efficacy.

Lipidoses

Lipid-storage diseases involve all three major lipid classes: neutral lipids (ie, cholesterol ester, fatty acid, and triglycerides), polar lipids (ie, glycolipids and phospholipids), and very polar lipids (ie, gangliosides).

GM2 Gangliosidoses

Hexosaminidase deficiency diseases result from a genetically determined deficiency of the enzyme hexosaminidase, which causes accumulation in cells (especially in neurons) of GM2 ganglioside and other glycosphingolipids.

For full activity, hexosaminidase requires two different subunits: the α-subunit, coded for by the HEXA locus on chromosome 15, and the β-subunit, coded for by the HEXB locus on chromosome 5. Three isozymes of hexosaminidase have a defined subunit structure: hexosaminidase A (αβ), hexosaminidase B (ββ), and hexosaminidase S (αα). Hexosaminidase A is required for cleavage of GM2 ganglioside, but the true substrate is the ganglioside bound to a protein activator whose deficiency also causes a GM2 gangliosidosis (the so-called "AB variant"). The GM2 gangliosidoses are classified according to the phenotype, the genetic locus, and the allele involved.

Progressive infantile encephalopathy was the most common clinical pattern in the past. The success of carrier screening in the Ashkenazi Jewish community dramatically reduced its incidence, and later onset variants are now seen more commonly. Hexosaminidase deficiencies show diverse phenotypes from infancy to adulthood. This diagnosis can be suspected with nearly any degenerative neurologic disorder, except demyelinating neuropathy or myopathy. Sensory dysfunction, ocular palsies, neurogenic bladder, and extraneural involvement are not prominent features.

The diagnosis is made by assaying hexosaminidase activity in blood serum and leukocytes and by sequencing the hexosaminidase genes.

Infantile Encephalopathy With Cherry-Red Spots

Three disorders in this group are well known: classic infantile Tay-Sachs disease (α-locus), infantile Sandhoff disease (β-locus), and the so-called "AB variant" (activator locus). Heterozygosity for α-locus mutations occurs in 1 in 30 Ashkenazi Jews (compared with 1 in 300 for the general population), accounting for the ethnic concentration of classic Tay-Sachs disease and genetic compounds containing α-locus mutations.

In all three conditions, the infants appear normal until 4 to 6 months of age. They learn to smile and reach for objects but do not sit or crawl. A myoclonic-jerk reaction to sound (traditionally, but misleadingly, termed *hyperacusis*) and the macular cherry-red spot are constant findings. The cherry-red macular spot is a funduscopic finding reflecting a combination of foveal atrophy and perifoveal lipid accumulation. The former improves visualization of the underlying choroid (whose color may range from bright red to brown in different individuals), which is contrasted with the more opaque surrounding lipid-laden retinal tissue. Cherry-red spots may be seen in GM2 and GM1 gangliosidoses, Niemann-Pick disease types A and B (but not in C), and sialidosis type 1 (cherry-red spot-myoclonus syndrome) and has been occasionally reported in Krabbe disease.

Affected infants become floppy and weak but have hyperactive reflexes, clonus, and extensor plantar responses. Visual deterioration, apathy, and loss of developmental milestones lead to a vegetative state by the second year. Seizures and myoclonus are prominent for the first 2 years. The infants eventually become decorticate. They need tube feeding, have difficulty with secretions, and are blind. Head circumference enlarges progressively to about the 90th percentile, from ages 1 to 3 years, and then stabilizes. Death is due to intercurrent infection, usually pneumonia. The disease is confined to the nervous system, apart from variable hepatosplenomegaly in Sandhoff disease.

By light microscopy, grossly ballooned neurons are found throughout the brain, cerebellum, and spinal cord. By electron microscopy, membranous cytoplasmic bodies (ie, distended lysosomes) are seen, with regularly spaced, concentric, dark, and pale lamellae.

GM2 ganglioside content is markedly increased in the brain and, to a much lesser degree, in the viscera. Other glycosphingolipids such as asialo-GM2 and globoside accumulate to a lesser degree.

The storage results from the deficiency of hexosaminidase. In classic Tay-Sachs disease, hexosaminidase A is absent and hexosaminidase B increased. Heterozygous carriers have a partial decrease of hexosaminidase A.

In infantile Sandhoff disease, hexosaminidases A and B are deficient. Carriers have partially decreased hexosaminidases A and B. In one form of the AB variant, a hexosaminidase A–activating protein is missing. Although levels of hexosaminidases A and B are increased, GM2 ganglioside cannot be cleaved. Diagnosis requires the use of the natural substrate, GM2 ganglioside, or direct testing for the activator or activator mutations. In a second form of the AB variant, the residual hexosaminidase A cleaves artificial but not sulfated artificial or natural substrate. Although this is detected as an AB variant, it is an α-locus disorder.

Late-Infantile, Juvenile, and Adult GM2 Gangliosidoses

These disorders present with dementia and ataxia with or without macular cherry-red spots. Spasticity, muscle wasting stemming from anterior horn cell disease, and seizures are frequently seen. Hexosaminidase A deficiency or hexosaminidases A and B deficiencies are found on biochemical study of serum, leukocytes, and cultured skin fibroblasts.

Other late-onset forms of GM2 gangliosidosis present as cerebellar ataxia or spinocerebellar ataxia. Hexosaminidase A or hexosaminidases A and B deficiencies are found on biochemical study.

Motor neuron disease resembling spinal muscular atrophy III may be the first evidence of late-onset GM2 gangliosidoses. Upper motor neuron findings may also be present, giving an amyotrophic lateral sclerosis-like phenotype.

Many, perhaps most, of these late-onset cases are compound heterozygotes. Diagnosis requires both enzyme assay and DNA sequencing.

A variety of therapeutic approaches to the GM2 gangliosidoses have shown disappointing results, including enzyme augmentation, hematopoietic stem cell transplantation, enzyme enhancement, and substrate reduction therapy. Gene therapy in animal models is promising, but has no proven benefit to date in humans.

GM1 Gangliosidosis

This group of disorders is characterized by the deficiency of GM1 ganglioside β-galactosidase and storage of GM1 ganglioside, asialo-GM1, keratan sulfate-like oligosaccharides, and glycoproteins. Other β-galactosidases such as those that cleave galactosylceramide and lactosylceramide are not deficient, and these compounds do not accumulate. There are at least three forms of deficiency of this enzyme: primary deficiency of β-galactosidase, causing infantile and late-infantile GM1 gangliosidosis and an adult form; combined neuraminidase and β-galactosidase deficiency; galactosialidosis; and combined deficiency of β-galactosidase and several other lysosomal enzymes in I-cell disease, mucolipidosis II (ML II). The latter two types are discussed under "Mucolipidoses" section.

FIGURE 139.1 Sagittal T2-weighted magnetic resonance imaging of an infant with GM1 gangliosidosis, showing macrocephaly and signal hyperintensity throughout the white matter.

Infantile GM1 Gangliosidosis

Infantile GM1 gangliosidosis is earlier in onset, more severe, and more rapidly progressive than infantile Tay-Sachs disease. Soon after birth, these infants become hypotonic, with poor sucking ability and slow weight gain. They have frontal bossing, coarsened features, large low-set ears, and an elongated philtrum. Gum hypertrophy, macroglossia, peripheral edema, and, often, faint corneal haze are noted. Strabismus and nystagmus may be seen. About half the patients develop macular cherry-red spots. Development is slow, and they do not sit or crawl. By the age of 6 months, liver and spleen are enlarged; joint stiffness and claw-hand deformities may be seen, and the skin is thickened. Seizures may develop. Infants typically die before age 2 years of pneumonia or cardiac arrhythmias.

The MRI of the brain may be normal initially, but as the head grows rapidly, diffuse signal hyperintensity appears throughout the white matter (Fig. 139.1). X-rays show changes similar to those of Hurler syndrome after 6 to 12 months, with anterior beaking of vertebral bodies and a J-shaped sella turcica. Peripheral blood smears show vacuolated lymphocytes, and foamy histiocytes are found in the bone marrow.

Diagnosis is suggested by the characteristic oligosaccharide pattern in urine and confirmed by assay of GM1 ganglioside β-galactosidase in blood leukocytes or cultured skin fibroblasts and mutation analysis.

Late-Infantile GM1 Gangliosidosis

Symptoms begin between ages 1 and 3 years, with gait ataxia, hypotonia, hyperreflexia, dysarthria, and speech regression. Seizures, dementia, and spastic quadriplegia lead to death, usually by pneumonia. Optic atrophy and evidence of anterior horn cell disease may be found. Corneas are clear, organomegaly is absent, and bone changes are scanty.

Juvenile and Adult GM1 Gangliosidosis

Juvenile and adult forms of this disorder may present with skeletal deformities or neurologic manifestations. Occasional corneal clouding, angiokeratomas, and hernias are observed. Changes in the gums, facial appearance, and the macula are typically absent. The neurologic manifestations include extrapyramidal and pyramidal signs, ataxia, oculomotor abnormalities, and behavioral changes. There are no approved treatments for any form of GM1 gangliosidosis, but scattered reports suggest that miglustat may benefit some patients with later onset forms of the disease. Gene therapy has shown benefit in murine models of the disease, but there are no human trial data available.

Fabry Disease

Fabry disease is an X-linked disorder in which the skin, kidney, peripheral and autonomic nervous systems, and blood vessels store trihexosylceramide, a breakdown product of globoside. Trihexosylceramide accumulates because of a deficiency of α-galactosidase A. Female heterozygotes are frequently clinically affected, albeit less severely and later than hemizygotes.

Symptoms usually commence in childhood or adolescence, with lancinating pains in the limbs, especially the feet and hands, often brought on by temperature changes and accompanied by paresthesia or abdominal crises. Anhidrosis and unexplained fever are common.

Angiokeratomas, which become more numerous with age, are purple; macular and maculopapular; hyperkeratotic; 1 to 3 mm in size; and with a predilection for the groin, buttocks, scrotum, and umbilicus. Glycolipid storage in the renal glomeruli and tubules begins with asymptomatic proteinuria in children; it progresses to renal failure and hypertension in the third or fourth decade. Glycolipid storage in blood vessel walls may cause stroke. Edema of the limbs, whorled corneal clouding (cornea verticillata) visible by slit lamp, and myocardial involvement may occur. ERT has been demonstrated to reverse lipid storage in the kidney, heart, and blood vessels and to produce corresponding improvement or reversal of renal impairment, pain, cardiac function, and cerebral blood flow. In some cases, renal transplant may still be required when renal failure supervenes. The lancinating pains may respond to phenytoin (5-8 mg/kg/d), carbamazepine (10-35 mg/kg/d), or gabapentin (10-40 mg/kg/d).

Heterozygous women may also be affected, but manifestations are less marked. Skin lesions are few or absent. Corneal opacity is more common. If renal or cardiac involvement occurs, they are later in onset and less severe. Fabry disease is diagnosed by finding decreased β-galactosidase activity in plasma and leukocytes and a mutation in the β-galactosidase gene.

Gaucher Disease

Gaucher disease is an autosomal recessive sphingolipidosis in which glucocerebroside is stored as a result of deficiency of glucocerebroside β-glucosidase (or glucocerebrosidase). At least four forms have been described: the infantile neuronopathic form, the juvenile neuronopathic form, the adult neuronopathic form, and the adult nonneuronopathic form.

These distinctions seem to be artificial, with overlapping manifestations occurring across a broad spectrum of phenotypes. The adult (nonneuropathic) form (type I) is more common in Ashkenazi Jews than in the general population. Diagnosis of all forms is made by demonstrating reduced glucocerebroside β-glucosidase activity in cultured skin fibroblasts or blood leukocytes and is further refined by demonstrating mutations in the β-glucosidase gene.

Type II (Infantile Neuronopathic) Gaucher Disease

This disease occurs in the first year of life, often in the first 3 months. The course is rapid, with developmental regression and

death before age 2 years. Affected infants lose weight, reflecting the mechanical compression of the gut and the hypercatabolic state associated with pronounced hepatosplenomegaly. The neurologic signs reflect severe brainstem dysfunction and include stridor, difficulty in sucking and swallowing, strabismus, retrocollis, spasticity, and hyperreflexia. Bilateral esotropia is typical. Later, affected children enter a vegetative state, becoming flaccid and weak. Seizures may occur. Macular cherry-red spots and optic atrophy do not occur.

Type III (Juvenile Neuronopathic) Gaucher Disease

Outside Europe and North America, type III Gaucher is the most common form of the disease. The manifestations range from a severe form, presenting in infancy as pulmonary infiltrates, splenomegaly, and cardiorespiratory failure, to a progressive myoclonic dementia in adolescents or adults (common in the northern provinces of Norrbotten and Västerbotten in Sweden). Horizontal supranuclear gaze palsy, with characteristic looping movements, in which the inability to generate horizontal saccades is partially compensated by generating vertical saccades accompanied by a horizontal head thrust, is an important clue to the diagnosis.

Type I (Adult) Gaucher Disease

These patients have visceral (eg, liver, lymph nodes, lung) and skeletal manifestations without primary neurologic disease. Multiple myeloma may be a late complication. It is most common in Ashkenazi Jews. Type 1 Gaucher disease presents at any age from infancy to the seventh decade. Splenectomy should be avoided unless ERT is not possible or the mechanical and hematologic manifestations are not otherwise controlled. Lesions of long bones, pelvis, or vertebral bodies may be painful. Severe cases may require surgical intervention, including joint replacement. ERT, with purified modified β-glucosidase (ie, alglucerase) or recombinant β-glucosidase (ie, imiglucerase), reverses all of the manifestations of type 1 Gaucher disease, provided that treatment begins before severe tissue damage has occurred. Substrate reduction therapy with miglustat or eliglustat is also approved by the U.S. Food and Drug Administration for therapy of type 1 Gaucher disease.

Adult Neuronopathic Gaucher Disease

Parkinsonism has been found to be more frequent in several studies of adults with Gaucher disease and in heterozygotes for glucocerebrosidase mutations. The relation now appears well established; the mechanism remains uncertain, and nonspecific lysosomal dysfunction may play a role in several neurodegenerative diseases, including parkinsonism.

Niemann-Pick Disease

This group of disorders includes several diseases that were grouped together in 1958 by Crocker and Farber on the basis of the overlapping pathology (ie, visceral foam cells) and biochemistry (ie, lysosomal storage of the glycosphingolipid sphingomyelin). Crocker subsequently proposed four groups. It is now recognized that his groups A and B are primary sphingomyelinase deficiencies, whereas groups C and D are allelic disorders, whose primary defect is not deficiency of a lysosomal hydrolase, but in intracellular lipid trafficking. Patients with types A and B Niemann-Pick disease have deficient activity of the sphingomyelin-cleaving enzyme acid, acid sphingomyelinase. The diagnosis should be suspected in patients with progressive hepatosplenomegaly, with or without cerebral symptoms. The bone marrow contains characteristic mulberry storage cells (ie, distinct from Gaucher cells). Decreased sphingomyelinase activity may be shown in cultured skin fibroblasts, leukocytes, or tissue.

Infantile Niemann-Pick Disease (Type A)

This is the most severe form of Niemann-Pick disease and occurs more commonly in Ashkenazi Jews than in the general population. Transient neonatal jaundice is followed by progressive hepatosplenomegaly; developmental regression and weight loss lead to dementia, hypotonia, and death by age 2 years. About one-half of patients develop macular cherry-red spots. Seizures are uncommon. Bone involvement is mild. Skin often has a brownish-yellow tinge. Most patients have diffuse haziness or patchy infiltrates in the lungs.

Diagnosis relies on the characteristic clinical picture, plus demonstration of near-total deficiency of sphingomyelinase in leukocytes or cultured skin fibroblasts, and by demonstrating mutations in the acid sphingomyelinase gene.

Juvenile Nonneuronopathic (Type B)

This form presents with asymptomatic splenomegaly or hepatosplenomegaly without neurologic disorder in infants, children, or adults, although cherry-red spots may be found. These patients have more residual sphingomyelinase (ie, 15%-20% of normal) than those with type A (ie, up to 10%). ERT is currently in clinical trials for Niemann-Pick disease type B.

Niemann-Pick Disease Type C

Niemann-Pick disease type C (NPC) may arise at any age from fetal life (ie, with ascites) to the fifth or sixth decades. Early-onset disease is dominated by hepatic and pulmonary failure, which are usually lethal in infancy. Classic childhood-onset disease more often presents insidiously with school failure and clumsiness that evolve into a progressive syndrome of ataxia, dystonia, and dementia. Vertical supranuclear gaze palsy is characteristic and almost invariably presents early, although often unrecognized. About 50% of patients have seizures, and 20% experience gelastic cataplexy. Hepatosplenomegaly is variable, and its absence does not rule out NPC. Genetic isolates have been described in Nova Scotia (formerly Niemann-Pick disease type D) and in Hispanics in Colorado and New Mexico.

Most patients with NPC are compound heterozygotes for mutations in NPC1; the gene product is a large transmembrane protein, localized to the late endosomal-lysosomal pathway. Dysfunction of this protein is associated with impaired trafficking of large molecules in this pathway, with accumulation of glycolipids, sphingomyelin, and cholesterol in lysosomes. The diagnosis rests on demonstration of this defect. Direct DNA analysis can be used as a first-line diagnostic test, but false negatives occur owing to the size of the gene and the large number of mutations (more than 300 recognized to date). The standard biochemical test requires demonstration of accumulation of free cholesterol in lysosomes, which is identified by filipin staining. This is an indirect index of the functional defect, with a significant number of variant cases with results that may be difficult to distinguish from heterozygotes. Assay of 3-beta, 5-alpha, 6-beta-cholestane triol in blood is a sensitive and generally specific marker of NPC, and is now established as a first-line diagnostic test. There is no approved therapy for NPC in the United Sates, although miglustat has been approved for management of its neurologic manifestations in the European Union and several other countries. In 2019, clinical trials were underway for *N*-acetyl-L-leucine, intrathecal and intravenous cyclodextrin,

and oral arimoclomol in NPC. Arimoclomol was granted breakthrough therapy status for NPC by the U.S. Food and Drug Administration in 2019.

A small number of cases of NPC are associated with mutations in a second gene, NPC2, whose gene product is a soluble, lysosomal protein. The NPC2 appears to interact with NPC1 either through transfer of unesterified cholesterol, responding to oxysterol signals, or some combination of both. Hematopoietic stem cell transplantation may be helpful in this disorder, although no controlled data are available.

Farber Disease

Farber disease is caused by deficiency of acid ceramidase. Infants with this disease have profound reduction of enzyme activity and present with painful swollen joints, hoarseness, vomiting, respiratory difficulty, or limb edema in the first few months of life, sometimes as early as 2 weeks of age. Most patients die of pulmonary disease before age 2 years, but some survive into adolescence. Hematopoietic stem cell transplantation has produced improvement in several measures, but does not prevent neurologic deterioration. Children with higher residual acid ceramidase activity (>10%) may present with a spinal muscular atrophy-progressive myoclonic epilepsy phenotype, distinct from that associated with SMN1 mutations, or with a less severe phenotype that includes optic nerve and retinal involvement, including cherry-red spots.

Cerebrotendinous Xanthomatosis (Cholestanol Storage Disease)

Cerebrotendinous xanthomatosis is an autosomal recessive disorder associated with elevated blood cholestanol levels and mutations in the sterol 27-hydroxylase gene (CYP27).

Patients with cerebrotendinous xanthomatosis often have early cognitive impairment and may have unexplained diarrhea beginning in infancy, but cataracts, tendon xanthomas, and progressive spasticity, usually associated with ataxia, commonly do not begin before adolescence or young adulthood. The spasticity and ataxia are severe and progressive. Speech is affected. Neuropathy may appear with distal muscle wasting. Sensory deficits and Babinski signs are seen. Pseudobulbar palsy develops terminally. Death from neurologic disease or myocardial infarction usually occurs in the fourth to sixth decade. Some patients have apparently normal mental function.

Tendon xanthomas are almost always seen on the Achilles tendon and may occur elsewhere. The cerebellar hemispheres contain large (ie, up to 1.5 cm) granulomatous xanthomas with extensive demyelination. The brainstem and spinal cord may be involved.

Treatment with chenodeoxycholic acid may prevent or reverse neurologic manifestations if started early in life.

Mucopolysaccharidoses

The MPS are defined by a characteristic phenotype and by the tissue storage and urinary excretion of acid mucopolysaccharide. They were originally considered a single disease, but eight clinical types, and numerous subtypes, are now known. Each is caused by deficiency of a lysosomal hydrolase required for degradation of one or more of three sulfated mucopolysaccharides: dermatan sulfate, heparan sulfate, and keratan sulfate.

Diagnosis is suspected based on the clinical picture, presence of excessive amounts of one or more acid mucopolysaccharides in urine, and is confirmed by demonstrating a specific enzyme defect. Urine screening tests for excess mucopolysaccharides are useful but are subject to false-positive and false-negative results. Positive screening tests require confirmation by quantitative and qualitative determination of urinary mucopolysaccharides and demonstration of the enzyme defect. False negatives are relatively frequent in Sanfilippo and Morquio syndromes. If clinical suspicion for an MPS is high, diagnostic evaluation should be pursued despite a negative urine screening test. Prenatal diagnosis of these disorders is available.

Hurler Syndrome (Mucopolysaccharidosis Type I)

This is the most severe of the MPS and is characterized by onset in infancy, progressive disability, and death usually occurring before 10 years of age. Nearly all the features found in other types are present in Hurler syndrome. Corneal clouding and lumbar gibbus occur in the first year of life, followed by the development of stiff joints with periarticular swelling; short, stubby hands and feet; claw hands; lumbar lordosis; chest deformity; and short stature by 2 or 3 years of age. The facies are characteristic, with thickened eyelids and lips; frontal bossing; bushy eyebrows; a depressed nasal bridge; ocular hypertelorism; enlarged tongue; noisy breathing; rhinorrhea; and widely spaced, peg-like teeth. Psychomotor slowing is followed by dementia, but seizures are not typical. Deafness is frequent, and few patients develop speech. Leptomeningeal thickening, arachnoid cysts, and hydrocephalus may occur. Cardiac murmurs resulting from valvular heart disease, coronary occlusion, and cardiac enlargement may occur and cause death. Abdominal distention is common, with inguinal and umbilical hernias and hepatomegaly. Corneal clouding progresses and, with retinal degeneration, impairs vision. Cervical cord compression with quadriplegia may occur.

Radiographic changes support the diagnosis of MPS, but do not reliably distinguish the various types. Findings include ovoid or beaked lumbar vertebrae, peg-shaped metacarpals, a J-shaped sella turcica, and spatulate ribs. Peripheral leukocytes and bone marrow cells contain metachromatic granules. Clear vacuoles are seen in hepatocytes and other cells. Zebra bodies containing lipids occur in the brain. Both dermatan sulfate and heparan sulfate accumulate in excess. The diagnosis is made by demonstrating severe deficiency of α-L-iduronidase in cultured skin fibroblasts and leukocytes. Mutation analysis of the α-L-iduronidase gene confirms the diagnosis and permits prenatal diagnosis.

Scheie syndrome, a milder allelic variant of Hurler syndrome, is characterized by juvenile onset of joint stiffness with the development of claw hands and deformed feet. A phenotype intermediate between that of the Hurler and Scheie syndromes is referred to as the *Hurler-Scheie compound*.

Hunter Syndrome (Mucopolysaccharidosis Type II)

Hunter syndrome includes mild and severe forms. Both are X-linked recessive and show iduronate-2-sulfatase deficiency. A Hunter-like phenocopy in girls with iduronate-2-sulfatase deficiency occurs in the context of total sulfatase deficiency (metachromatic leukodystrophy [MLD], Austin type).

Boys with the severe form experience juvenile-onset joint stiffness, typical facial features (Fig. 139.2), dysostosis multiplex, hepatosplenomegaly, diarrhea, dwarfing, and mental deterioration. Progressive deafness is prominent. Pigmentary retinal deterioration, papilledema, and hydrocephalus may be seen. Nodular or pebbled-skin change over the scapulae and absence of corneal clouding are important features distinguishing Hunter syndrome from Hurler syndrome. Patients usually die as teenagers.

Patients with the mild form of Hunter syndrome may be asymptomatic or have only mild systemic findings.

FIGURE 139.2 Mucopolysaccharidosis type II (Hunter syndrome); note periorbital fullness, increased tissue thickness of the lips and cheeks, and hearing aid.

Sanfilippo Syndrome (Mucopolysaccharidosis Type III)

Patients with this syndrome outnumber all other forms of MPS combined. They exhibit progressive cognitive impairment, mild somatic involvement, and urinary excretion of heparan sulfate alone. Four biochemically distinct forms reflect four metabolic steps required for the degradation of heparan, but not dermatan or keratan, sulfate. Sanfilippo patients have juvenile-onset dementia, with delay or deterioration of speech or school performance. Children presenting with psychiatric disorder, intellectual disability, or dementia should be carefully examined for subtle changes in facial features, hepatosplenomegaly, hirsutism, joint stiffness, and radiographic changes of dysostosis multiplex. These patients deteriorate neurologically, with progressive dementia, spastic quadriparesis, tetraballism, athetosis, incontinence, and seizures. Cardiac involvement may occur. Corneal clouding is absent. Bone changes, short stature, and organomegaly are slight. Patients may die in adolescence or survive into the third decade of life.

The diagnosis is made by the characteristic clinical picture, increased heparan sulfate in the urine, and by demonstration of the specific enzyme defect and mutations in the relevant gene. Screening tests for mucopolysacchariduria may be negative in Sanfilippo syndrome. There is currently no therapy of proven efficacy in MPS III, although ERT, substrate reduction therapy, and gene therapy have been explored in humans and animal models.

Mucolipidoses

The MLs resemble the Hurler phenotype but lack excess urinary mucopolysaccharide, having instead, excess urinary oligosaccharides or glycopeptides, most of which are fragments of more complex structures. Urinary thin-layer chromatography for oligosaccharides is a useful screening test.

Sialidosis (Mucolipidosis I)

Patients with sialidoses have deficiency of α-L-neuraminidase, also known as *sialidase* encoded by the NEU1 gene. In most forms, sialic acid–containing glycoproteins, oligosaccharides, and glycolipids accumulate in tissue, and sialyloligosaccharides are excreted in urine.

The diagnosis is based on clinical findings; the presence of abnormal sialyloligosaccharides in the urine; deficiency of the appropriate sialidase in cultured skin fibroblasts, tissue, or leukocytes; and demonstration of mutations in NEU1. There are at least two distinct lysosomal sialidases.

In addition to the isolated sialidase deficiencies, two other groups of MLs have sialidase deficiency. In one, galactosialidosis, both sialidase and β-galactosidase are deficient because a stabilizing protein they share is defective. In the second group, ML II and ML III, sialidase and several other lysosomal hydrolases are deficient owing to deficient activity of the phosphotransferase that is responsible for creating the mannose-6-phosphate motif that targets enzymes to the lysosome.

Sialidoses with isolated sialidase deficiency have a highly variable clinical picture. Neonate and infants are categorized as having sialidosis type 2. Neonates with congenital sialidoses have hydrops fetalis, hepatosplenomegaly, and short survival times. Infants with nephrosialidosis resemble the Hurler phenotype and develop macular cherry-red spots and renal disease. Children with sialidosis type 1 (also known as *ML I*), a milder disorder, are similarly affected but develop ataxia, myoclonic jerks, and seizures. The mildest form is the cherry-red spot myoclonus disorder, in which adolescents, who are usually intellectually normal, develop macular cherry-red spots, myoclonus, and myoclonic seizures. There is a predilection for individuals of Italian descent.

There is no disease-modifying therapy for any form of ML I.

Mucolipidoses II and III

ML II, or I-cell disease, and ML III, or pseudo-Hurler polydystrophy, are allelic autosomal recessive disorders associated with deficiency of the enzyme, glycoprotein *N*-acetylglucosamine-1-phosphotransferase, whose activity is required for mannose-6-phosphate targeting of glycoproteins, including many lysosomal hydrolases, from the Golgi apparatus to the lysosome. These diseases are associated with mutations in the GNPTAB and GNPTG genes, which encode the α/β and γ subunits of the enzyme, respectively. Study of a sample of more than 1,000 unrelated individuals with nonsyndromic persistent stuttering identified 164 individuals who carried rare nonsynonymous coding variants in one of these genes, without manifestations suggestive of ML.

ML II is a severe disorder that resembles Hurler syndrome without corneal clouding. Cultured fibroblasts contain coarse inclusions (I-cells). Diagnosis is made by finding excess sialooligosaccharides in the urine and deficiencies of multiple lysosomal enzymes in cultured skin fibroblasts, with elevated levels of these enzymes in plasma. In brain and viscera, only β-galactosidase is consistently deficient.

ML III is a milder clinical disorder than ML II that may present with joint stiffness, carpal tunnel syndrome, avascular necrosis of bone, or mild intellectual impairment. Pamidronate may be helpful in managing the bony lesion of ML III, particularly hip disease. There is no disease-modifying therapy for ML II or ML III.

Mucolipidosis IV

ML IV is an autosomal recessive disorder associated with severe intellectual disability, defects in motor and speech function, corneal clouding and progressive retinal degeneration leading to blindness, and a shortened life span. Corneal clouding may present as early as 6 weeks of age. The disease was initially thought to occur almost exclusively in Ashkenazi Jews, but cases have now been identified from around the world, although only a little over 100 individuals have been reported in total. Achlorhydria is universal, and measurement of elevated serum-gastrin levels is a convenient and reliable screening test for ML IV. Diagnosis may now be made by mutation analysis of the MCOLN1 gene, which codes for mucolipin, also known as *TRPML1*, a member of the transient receptor potential family of proteins. Dysfunction of TRPML1 leads to impairments in endosomal-lysosomal trafficking, autophagy, lysosomal exocytosis, mammalian target of rapamycin complex 1 signaling, and heavy metal homeostasis. Miglustat has slowed progression in the ML IV mouse, and fingolimod has been demonstrated to inhibit astrocytic inflammation in the same model, but no disease-modifying therapy is yet available for affected humans.

Neuronal Ceroid Lipofuscinoses

The NCLs are a family of lysosomal diseases characterized by varying degrees of progressive dementia, epilepsy, and visual impairment associated with retinal pigmentation and profound cortical atrophy. They were previously defined by histologic and ultrastructural features and a plethora of confusing and inconsistently applied eponyms, but are now classified according to genotypes. The common pathologic features include neurons engorged with periodic acid–Schiff (PAS)-positive and autofluorescent material on light microscopy and typical profiles, including granular osmiophilic deposits and curvilinear and fingerprint bodies (or combinations of these), on electron microscopy. Although the signs and symptoms are confined to the nervous system, the abnormal cytosomes are widely distributed in skin, muscle, peripheral nerves, leukocytes, urine sediment, and viscera.

Thirteen genes have been associated with 14 NCL loci; the gene associated with 1 locus (CLN9) has not yet been identified. All are autosomal recessive, except for the Parry form of adult NCL, which is associated with dominant mutations in DNAJC5. Some phenotypes may be associated with mutations in several genes (such as adult NCL, associated with mutations in cathepsin D [CTSD], PPT1, CLN3, CLN5, CLN6, CTSF, GRN), and some genes, such as PPT1, may cause several different phenotypes, which is associated with infantile, late-infantile, and juvenile NCL.

The diagnosis of PPT1-, TPP1-, and CTSD-deficient forms of NCL may be made by enzyme assay and confirmed by mutational analysis. A database listing NCL mutations is available online at https://www.ucl.ac.uk/ncl-disease/.

Supporting investigations include an abnormal electroretinogram in the infantile, late-infantile, and juvenile forms and electron microscopic examination of tissue (ie, skin, nerve, muscle, or rectal biopsy for autonomic neurons). Abnormal autofluorescence is seen on examination of frozen section of biopsied muscle, enabling rapid diagnosis.

The most frequent phenotypes are late infantile (NCL2) and juvenile (NCL3). The former presents between 2 and 4 years with seizures, associated with developmental regression, ataxia, myoclonus, and spasticity. Retinal degeneration occurs later in the course and eventually leads to blindness.

Juvenile NCL begins in the latter half of the first decade with progressive loss of vision and later onset of epilepsy. Patients may survive into the fourth decade.

Rapid and accurate diagnosis of NCL is essential, now that disease-modifying therapy is available, or in clinical trials. Cerliponase alfa, administered directly into the cerebral ventricles, stabilizes NCL2 and has been approved by the U.S. Food and Drug Administration for this indication. Trials of gene therapy are in progress for CLN2, CLN3, and CLN6. Recombinant human pro-CTSD is under investigation in CTSD-deficient hippocampus slice cultures in vitro, retinal cells in vivo, and in the CLN10 mouse model.

Leukodystrophies

The leukodystrophies are progressive, genetic metabolic disorders causing dysmyelination, in contrast to leukoencephalopathies that are often acquired.

Disorders such as Krabbe disease, MLD (which are lysosomal diseases), adrenoleukodystrophy (ALD) (discussed with other peroxisomal disorders), Alexander disease, and classic Pelizaeus-Merzbacher disease (PMD) were defined by traditional clinical and pathologic investigations. Careful clinical and magnetic resonance phenotyping combined with molecular biology have led to the identification of a variety of additional leukodystrophies, including childhood ataxia with central hypomyelination (also known as *vanishing white matter disease* [VWM]), megalencephalic leukoencephalopathy with subcortical cysts, hypomyelination of the basal ganglia and cerebellum, oculodentodigital dysplasia, and leukoencephalopathy involving the brainstem and spinal cord with lactate elevation. This leaves a heterogeneous, but shrinking group, of unclassified leukodystrophies, historically referred to as *orthochromatic or sudanophilic leukodystrophies*. Diffuse sclerosis (Schilder disease) is included in this chapter, although it resembles multiple sclerosis more than traditional leukodystrophies.

Metachromatic Leukodystrophy

MLD comprises a group of autosomal recessive disorders with degeneration of central and peripheral myelin, striking metachromasia of the stored substances, primarily sulfatides, and deficiency of the sulfatide-cleaving enzyme, sulfatase A, also called *arylsulfatase A* (ARSA). Late-infantile onset disease is most common.

The diagnosis of MLD is complicated by the existence of sulfatase A pseudodeficiency, an autosomal recessive condition in which sulfatase A activity is greatly diminished in enzyme assays using artificial substrates, but there is no neurologic disease. An additional complication is the requirement of sulfatase A for the sulfatide-activator protein. Patients with genetic deficiency of sulfatide-activator protein may have MLD, but the commonly used enzyme assays may fail to diagnose this condition.

Late-Infantile Metachromatic Leukodystrophy

Affected infants have onset of difficulty in walking after the first year of life, usually between ages 12 and 30 months. Flaccid paresis and diminished, or absent, tendon reflexes are typical, but occasionally, spastic paresis develops. Genu recurvatum, hyperextension of the knee, may be noted. Progressive dementia and dysarthria follow.

Peripheral neuropathy leads to loss of tendon reflexes and may be accompanied by limb pain. Later, patients become bedridden and quadriplegic, with feeding difficulties, bulbar and pseudobulbar palsies, and optic atrophy. Children so affected

usually die in the first decade of life, blind and in a vegetative state. Investigations show increased CSF protein content, impaired gallbladder function, and increased urinary-sulfatide excretion. Before the availability of enzyme assays and molecular sequencing, the diagnosis could be confirmed by the demonstration of metachromatic lipids on sural nerve biopsy,

Sulfatide accumulates in brain, peripheral nerves, and some extraneural tissues (eg, kidney). Sulfatide causes brown metachromasia, with acetic acid–cresyl violet staining in glial cells, Schwann cells, myelin lamellae, and neurons. Characteristic "tuffstone" bodies are seen by electron microscopy.

The diagnosis is based primarily on enzyme analysis, supported by ARSA gene sequencing. Trials of intrathecal ERT with recombinant human ARSA are currently in progress in subjects with late-infantile MLD.

Late-Onset Metachromatic Leukodystrophy

Juvenile metachromatic leukodystrophy patients resemble those with late-infantile MLD but for the later onset of symptoms (usually between 3 and 10 y) and slower progression of the disease. Emotional disturbance or dementia are more common presentations, although gait disorder may be the initial symptom. Nystagmus and tremor may be noted. Nerve conduction velocities are slowed and CSF protein concentrations are elevated. The diagnosis can usually be suspected from MRI or the brain, which shows diffuse, confluent signal hyperintensity in the white matter of the centra semiovale, with a striated "tigroid" appearance (Fig. 139.3).

MLD commonly starts in adults in the third or fourth decade as a psychiatric disorder (mimicking schizophrenia) or progressive dementia. Other findings may include truncal ataxia, hyperactive reflexes, and seizures. Both psychiatric and motor manifestations may coexist in association with certain mutations. The CSF protein concentration is usually not elevated. The illness runs a protracted course, averaging 15 years.

FIGURE 139.3 Axial T2-weighted magnetic resonance imaging of an 18-year-old with metachromatic leukodystrophy, illustrating the characteristic "tigroid" appearance of the white matter.

Krabbe (Globoid Cell) Leukodystrophy

Patients are normal at birth but may have subtle findings, such as fisting in the first few weeks. At 3 to 6 months, irritability, inexplicable crying, fevers, rigidity, seizures, feeding difficulty, vomiting, and slowing of cognitive and motor development become apparent. Later, psychomotor regression occurs, accompanied by increasing tone and extensor posturing. Reflexes may be increased before being lost. Optic atrophy is frequent. Patients may develop flaccidity or flexor postures before death, at about 2 years of age. Most children have acquired microcephaly, but macrocephaly with hydrocephalus is occasionally observed.

The CSF protein is increased, and nerve conduction velocities are slowed. Galactocerebrosidase activity is deficient in serum, leukocytes, and cultured skin fibroblasts; the enzyme is encoded by GALC. Psychosine, a substrate for this enzyme, is increased at least 200-fold over levels in the normal brain. Psychosine toxicity is probably the cause of the disease based on studies showing its ability to produce characteristic lesions in animal models.

A few patients with juvenile onset and slower progression of dementia, optic atrophy, and pyramidal tract signs, without neuropathy, have had galactocerebrosidase deficiency. An adult-onset disorder with a similar but more slowly progressive course resembling a spinocerebellar ataxia has been described.

Hematopoietic stem cell transplantation in the first 3 weeks of life is effective in prolonging life in infants with early infantile Krabbe disease, although many such children have significant residual neurologic disabilities. The availability of this therapy has led to the implementation of newborn screening for Krabbe disease in several states in the United States. The effectiveness of hematopoietic stem cell transplantation in older patients with Krabbe disease is controversial.

Alexander Disease

Alexander disease is an autosomal dominant progressive leukodystrophy associated with gain-of-function mutations in the GFAP gene that encodes glial fibrillary acidic protein. As such, it is a primary disorder of astrocytes, in contrast to other leukodystrophies, in which the major affected cell type is the oligodendrocyte. The classic presentation occurs in infants, who manifest macrocephaly, developmental regression, seizures, and progressive spasticity. The MRI shows a pattern of frontally predominant white matter hyperintensity, sometimes with cavitation, with periventricular hyperintensity with or without enhancement and "garlands," and increased signal intensity in the medulla, middle cerebellar peduncles, and long tracts, with or without atrophy (particularly in later onset cases) (Figs. 139.4 and 139.5). Some patients develop hydrocephalus secondary to compression of the aqueduct of Sylvius by swollen midbrain astrocytes. Cases in which tumor-like lesions occur have been reported. The affected areas show accumulation of Rosenthal fibers.

In adolescents and adults, Alexander disease is much less likely to be associated with macrocephaly and may be manifest as cognitive and emotional disturbance, with relatively mild long tract signs or ataxia; persistent vomiting may be prominent. Oculopalatal myoclonus has been described as a classical finding in such patients but is often absent. The anatomic and clinical patterns overlap with neuromyelitis optica, which is an acquired disorder of astrocytes, in which antibodies are directed at aquaporin, expressed in water channels in astrocytes.

There is no disease-modifying therapy available for Alexander disease, but given its prolonged course, particularly in later onset forms, vigorous supportive treatment is strongly encouraged.

FIGURE 139.4 Axial T2 fluid-attenuated inversion recovery magnetic resonance imaging of a 12-year-old with Alexander disease, showing frontal predominant white matter hyperintensity with cavitation and periventricular hyperintensity.

Antisense suppression of GFAP expression in mouse models of Alexander disease has produced positive effects pathologically and in the clinical phenotype of the affected animals.

Pelizaeus-Merzbacher Disease

PMD is an X-linked hypomyelinating disorder associated with duplications, deletions, and point mutations in the gene encoding central proteolipid protein (PLP1). Infantile forms of the disease present with profound hypotonia and unusual pendular nystagmus with gray optic disks. The most severely affected infants do not develop further and succumb to their illness in the first few years of life, but some boys make developmental gains and survive into the second decade, although they rarely walk or talk. In those who survive into childhood, intellectual disability, progressive ataxia, spasticity, and choreoathetosis are often observed. The MRI in PMD shows profound hypomyelination, with reduced white matter volume. Some patients with mild mutations in PLP1 have a slowly progressive spastic paraplegia, classified as spastic paraplegia 2. There is no established therapy for PMD, but a trial of human CNS stem cells implanted into the cerebral hemispheres in four boys reported that subjects were alive at the end of the study period; two of these subjects developed specific alloantibodies against the donor cells. The clinical responses were variable, but the subjects were generally stable. A study of the ketogenic diet in the mouse model of PMD showed evidence of benefit, in contrast to cholesterol supplementation, which was not of benefit in two patients.

FIGURE 139.5 Axial T2 fluid-attenuated inversion recovery magnetic resonance imaging of a 12-year-old with Alexander disease, showing increased signal in the medulla, middle cerebellar peduncles, and long tracts.

A number of families, who lack mutations in PLP1, have been recognized with a PMD-like illness. Recessive mutations in GJA12/GJC2, which encodes a protein essential in gap junction formation in myelin, have been identified in some such families; TUBB4A mutations have been identified in another case mimicking PMD.

Vanishing White Matter Disease

In 1994, Schiffmann and colleagues described four girls with progressive ataxic diplegia, whose imaging studies showed confluent white matter disease early in the course of the illness; the peripheral nerves and intellect were spared, and extensive investigation for previously described leukodystrophies was uninformative. Biopsy specimens showed hypomyelination, demyelination, gliosis, and reduced quantities but qualitatively normal lipids. The MRS showed reduced *N*-acetylaspartic acid, choline, and creatine restricted to the white matter. They named this disorder *childhood ataxia with central hypomyelination*. A year earlier, Hanefeld et al had described three children with identical features, whose disease they named *myelinopathia centralis diffusa*.

In 1997, van der Knaap's group described nine more patients with this phenotype. They emphasized the unusual combination of slowly progressive ataxia with episodic decompensation in the face of minor trauma (motor change) or intercurrent infection (coma). They also recognized that the white matter signal eventually disappeared, to be replaced by CSF intensity signal. The latter was found to correspond to extensive cystic degeneration of the cerebral white matter with preserved cortex in an autopsied case. Subsequent studies have emphasized the relative preservation of oligodendrocytes with abundant foamy cytoplasm and scarcity of astrocytes as the specific neuropathologic hallmark of the disease.

Van der Knaap's descriptive term, vanishing white matter disease, *VWM*, which emphasizes the most dramatic aspect of this illness, has subsequently dominated the literature. Myelinopathia centralis diffusa was never widely accepted, but childhood ataxia with central hypomyelination is still encountered, most often in tandem with VWM.

VWM is caused by mutations in any one the genes coding for the subunits of the eukaryotic translation initiation factor 2 b (eIF2B); VWM is the first disease recognized that is associated with mutations in a translation factor. The eIF2B protein is the major regulator of protein synthesis under conditions of mild stress, such as temperatures up to 41°C. The gene is expressed in all tissues, yet VWM is restricted to the cranial white matter. In vitro studies of VWM brain have shown that all three pathways of the unfolded protein response are inappropriately activated

but only in white matter. This remarkable specificity remains unexplained, as is the case for other disorders involving mutations of DNA housekeeping machinery that are expressed in specific regions of the nervous systems, such as spinal muscular atrophy.

As has proven to be the case in other inborn errors of metabolism, the appearance and use of a diagnostic test for VWM has been followed by the recognition of a broader range of phenotypes than those originally described. Thus, Cree leukoencephalopathy and ovarioleukodystrophy have both been shown to be associated with mutations in eIF2B. The former is an autosomal recessive leukodystrophy, lethal in the first 2 years, that is observed in the native North American Cree and Chippewayan population where high rates of consanguinity prevail. Death in the context of a common viral infection may be the presenting feature. The latter phenotype can be associated with either primary or secondary amenorrhea and a more indolent neurologic course, with variable dementia, gait ataxia, sphincter dysfunction, optic atrophy, and episodic decompensation. Other unusual features have been reported, including marked macrocephaly in a child with survival into the third decade, adult presentation with psychosis, and precipitation of symptoms after being frightened by a horse.

Despite the availability of DNA diagnostic testing, confirmation of the diagnosis may be technically difficult because VWM can result from mutations in any of the five genes coding for subunits of eIF2B and because there is a high frequency of private and low-frequency mutations in the cases described to date.

There is, as yet, no specific treatment for VWM. Avoidance of the precipitating factors is obviously advisable, but difficult to accomplish in practice, given the propensity of children to bump their heads and catch colds. A small molecule (integrated stress response inhibitor [ISRIB]) that specifically activates eIF2b has shown promise in cellular models of this disease, although this has not yet been reproduced in whole animal models. In contrast, transplantation of murine glial progenitor cells has shown promise in mouse models of VWM.

Diffuse Sclerosis

Schilder described new syndromes of diffuse demyelination of the brain in 1912, 1913, and 1924. Later advances identified the 1913 description as one of ALD, and the 1924 patient had subacute sclerosing panencephalitis. Nevertheless, the 1912 case delineated a clinical and pathologic syndrome that is still seen, even though cases of uncomplicated diffuse sclerosis are so few that each encounter results in a case report. In 1994, a review counted 12 cases since 1912; a subsequent review added 16 more between 1998 and 2008.

Schilder disease was and is regarded as a variant of multiple sclerosis, but the etiology and pathogenesis are not known.

At autopsy, there are large areas of demyelination in the centrum ovale, with relative preservation of axons. Subcortical U-fibers are often spared. In acute lesions, there is perivascular infiltration by $CD45^+$ lymphocytes and giant cells; there may be necrosis. The lesions are similar to those of multiple sclerosis. In fact, in most cases that include large areas of demyelination, there are also smaller, more typical lesions of multiple sclerosis. For these cases, the term *transitional sclerosis* has been used. It is assumed that the small lesions coalesce to form the large ones. The demyelinating lesions contain $CD68^+$ macrophages and GFAP-positive astrocytes with long processes.

The clinical syndrome is a leukoencephalopathy, with progressive dementia, psychosis, corticospinal signs, and loss of vision caused by either optic neuritis with papilledema or cerebral blindness. Brainstem signs may include nystagmus and internuclear ophthalmoplegia. The disease is relentlessly progressive, with average survival of about 6 years but sometimes as long as 45 years.

Diagnosis depends on imaging; MRI shows gadolinium enhancement of large white matter lesions. There may be CSF pleocytosis with evidence of intrathecal synthesis of gamma globulin and oligoclonal bands. Brain biopsy may be needed to identify the few cases that simulate mass lesions. A retrospective analysis of the CSF profile of all patients reported in the literature between 1960 and 2018 found a substantial lack of oligoclonal bands, as well as a lack of EBV serum antibodies, and the so called measles/rubella/zoster reaction. The authors concluded that diffuse sclerosis is immunologically distinct from multiple sclerosis and that the features are more similar to those reported in patients with myelin oligodendrocyte glycoprotein-positive encephalitis, neuromyelitis optica spectrum disorders, or Baló concentric sclerosis.

Steroid therapy was followed by complete resolution of lesions or only minor sequelae in 10 of 16 cases reported in the decade up to 2008; 9 cases subsequently recurred. Intravenous immunoglobulin has been used successfully; surgical resection is occasionally required to manage herniation complicating a large lesion. Recurrent disease following steroid therapy has been reported in one affected teenager.

Disorders of Carbohydrate Metabolism

Glycogen Storage Diseases

Abnormal metabolism of glycogen and glucose may occur in a series of genetically determined disorders, each representing a specific enzyme deficiency (Table 139.5). The signs and symptoms of each disease are largely determined by the tissues in which the enzyme defect is expressed. Virtually all enzymes of glycogen metabolism, including tissue-specific isoforms or subunits, have been assigned to chromosomal loci, and the corresponding genes have been cloned and sequenced. Numerous mutations have been identified and genotype: Phenotype correlation is taking shape.

Severe fasting hypoglycemia may result in periodic episodes of lethargy, coma, convulsions, and anoxic brain damage in glucose-6-phosphatase deficiency (glycogenosis type I) or in glycogen synthetase deficiency. The liver is enlarged in both diseases. Clinical manifestations tend to become milder in patients who survive the first few years of life.

The CNS is directly affected by the enzyme defect in generalized glycogen storage diseases, even though neurologic symptoms are lacking in some disorders, and in others, it may be ascribed to liver rather than to brain dysfunction. The following enzyme defects seem to be generalized: acid maltase (type II), debrancher (type III), brancher (type IV), and phosphoglycerate kinase (type IX).

Acid alpha glucosidase (acid maltase; acid α-1,4 and α-1,6 glucosidase) deficiency is a lysosomal disorder due to mutations in the GAA gene on chromosome 17. In the infantile form of acid maltase deficiency, first described by Johannes Pompe in 1932 (Pompe disease), pathologic involvement of the CNS has been documented, with accumulation of both free and intralysosomal glycogen in all cells, especially spinal motor neurons and neurons of the brain stem nuclei. Peripheral nerve biopsy specimens show accumulation of glycogen in Schwann cells. The profound generalized weakness of infants with Pompe disease is probably due to combined effects of glycogen storage in muscle,

TABLE 139.5 Classification of Glycogen Storage Disease

Type	Affected Tissues	Clinical Presentation	Glycogen Structure	Enzyme Defect	Mode of Transmission
I	Liver and kidney	Severe hypoglycemia; hepatomegaly	Normal	Glucose-6-phosphatase	AR
II	—	—	—	—	—
Infancy	Generalized	Cardiomegaly; weakness; hypotonia; death <1 y	Normal	—	AR
Childhood	Generalized	Myopathy simulating Duchenne dystrophy; respiratory insufficiency	Normal	Acid maltase	AR
Adult	Generalized	Myopathy simulating limb-girdle dystrophy or polymyositis; respiratory insufficiency	Normal	—	AR
III	Generalized	Hepatomegaly; fasting hypoglycemia; progressive weakness	PLD	Debrancher	AR
IV	Generalized	Hepatosplenomegaly; cirrhosis of liver; neuromuscular disease; APBD	Polyglucosan	Brancher	AR
V	Skeletal muscle	Intolerance to intense exercise; cramps; myoglobinuria	Normal	Muscle phosphorylase	AR
VI	Liver; RBC	Mild hypoglycemia; hepatomegaly	Normal	Liver phosphorylase	AR
VII	Skeletal muscle; RBC	Intolerance to intense exercise; cramps; myoglobinuria	Normal (± polyglucosan)	PFK-M	AR
VIII	Liver	Asymptomatic hepatomegaly	Normal	Phosphorylase kinase	XR
	Liver and skeletal muscle	Hepatomegaly; growth retardation; hypotonia	Normal	Phosphorylase kinase	AR
	Skeletal muscle	Exercise intolerance; myoglobinuria	Normal	Phosphorylase kinase	XR; AR (?)
	Heart	Fatal infantile cardiomyopathy	Normal	Phosphorylase kinase	AR
IX	Generalized	Hemolytic anemia; seizures; mental retardation	Normal (?)	PKG	XR
		Intolerance to intense exercise; myoglobinuria			
X	Skeletal muscle	Intolerance to intense exercise; myoglobinuria	Normal (?)	PGAM-M	AR
XI	Skeletal muscle	Intolerance to intense exercise; myoglobinuria	Normal (?)	LDH-M	AR
XII	Skeletal muscle; RBC	Exercise intolerance	Normal (?)	Aldolase A	AR
XIII	Skeletal muscle	Exercise intolerance	Normal (?)	β-Enolase	AR
	Generalized	Myoclonus epilepsy (Lafora disease)	Polyglucosan	Laforin	AR
XIV	Generalized	Hepatopathy, myopathy, cardiomyopathy, malignant hyperthermia, bifid uvula	Normal	PGM1	AR
XV	Skeletal muscle, heart	Myopathy, cardiac arrhythmias	Glycogen depletion	GYG1	AR
0	Muscle	Cardiomyopathy; exercise intolerance	Glycogen deficiency	Glycogen synthetase	AR

Abbreviations: ?, not yet definitively documented; APBD, adult polyglucosan body disease; AR, autosomal recessive; GYG1, glycogenin 1; LDH-M, muscle lactate dehydrogenase; PFK-M, muscle phosphofructokinase; PGAM-M, muscle phosphoglycerate mutase; PGM1, phosphoglucomutase 1; PKG, phosphoglycerate kinase; PLD, phosphorylase-limit dextrin; RBC, red blood cell; XR, X-linked recessive.

anterior horn cells, and peripheral nerves. In four patients with the childhood form of acid maltase deficiency, increased glycogen deposition in neurons of the brain stem was related to fatal intractable hyperpyrexia. No morphologic changes were seen in the CNS of a patient with adult-onset acid maltase deficiency despite marked decrease of enzyme activity. However, the enzyme defect predisposes to dilated arteriopathy and cerebral aneurysm formation, sometimes leading to stroke. ERT is now standard of care for Pompe disease and has been shown to diminish the number of infants requiring ventilator support and generally extend lifespan, without completely reversing the manifestations of the disease. The incomplete response to ERT is attributed to its inability to correct the impaired autophagy, which is characteristic of this disorder. Owing to these shortcomings, additional approaches to treatment, including the use of antisense oligonucleotides to modify splice sites, stop codon readthrough therapy, enzyme enhancement/chaperone therapy, and gene transfer therapy, are under active study in Pompe disease.

Patients with **debrancher deficiency** (glycogenosis type III, due to mutations in the AGL gene on chromosome 1, have hepatomegaly, fasting hypoglycemia, and seizures in infancy and childhood, which usually remit around puberty. Muscle biopsy shows a vacuolar myopathy, with evidence of impaired autophagy. Although overt signs of peripheral neuropathy are rare, abnormal deposits of glycogen have been documented both in axons and in Schwann cells and may explain, in part at least, the distal wasting and mixed EMG pattern observed in adult patients with neuromuscular involvement. Historically, type III glycogen storage disease patients have been treated with cornstarch, which provides a continuous source of glucose to prevent

hypoglycemia, and minimize ketosis, which may have detrimental effects in growing children. Case reports have suggested benefit from a modified ketogenic diet in adults, for whom ketosis poses fewer problems than in children.

In **branching enzyme deficiency** (glycogenosis type IV, due to mutations in the GBE1 gene on chromosome 3), the clinical picture is typically dominated by liver disease, with progressive cirrhosis and chronic hepatic failure causing death in childhood. However, the neuromuscular system is involved more often than it was previously realized, with fetal, congenital, juvenile, or adult presentations. The severe congenital myopathy, sometime associated with cardiomyopathy, may simulate spinal muscular atrophy type I (Werdnig-Hoffmann disease). Deposits of a basophilic, intensely PAS-positive material that is partially resistant to β-amylase digestion (polyglucosan) have been found in all tissues; in the CNS, spheroids composed of branched filaments were present in astrocytic processes, particularly in the spinal cord and medulla. Ultrastructurally, the storage material was composed of aggregates of branched osmiophilic filaments, 6 nm in diameter often surrounded by normal glycogen particles.

In **phosphoglycerate kinase deficiency** (glycogenosis type IX, due to mutations in the PGK1 on the X chromosome), the type and severity of clinical manifestations vary in different genetic variants of the disease and are probably related to the severity of the enzyme defect in different tissues. In several families, the clinical picture was characterized by the association of severe hemolytic anemia with intellectual disability and seizures.

Lafora Disease and Other Polyglucosan Storage Diseases

Several diseases are associated with the accumulation of an unusual form of glycogen referred to as *polyglucosan*. Polyglucosan differs from glycogen in having very long strands (which confer insolubility), fewer branching points, and similarities to the plant carbohydrate, amylopectin.

The most prominent of these disorders include Lafora disease and adult polyglucosan body disease (APBD), but polyglucosan storage also occurs in glycogen storage diseases types 4, 7, and 15; polyglucosan body myopathies types I and II; and hypertrophic cardiomyopathy type 6.

Myoclonus epilepsy with Lafora bodies (Lafora disease) is an autosomal recessive disease that is characterized by the triad of epilepsy, myoclonus, and dementia. Inconstant other neurologic manifestations include ataxia, dysarthria, spasticity, and rigidity. Classically, onset is in adolescence, and the course progresses rapidly to death, which occurs between 17 and 24 years in 90% of patients. Negative criteria or manifestations that imply some other disease include onset before 6 or after age 20 years, optic atrophy, macular degeneration, prolonged course, or normal intelligence. Epilepsy, with predominantly occipital seizures, is the first manifestation in most patients; status epilepticus is common in terminal stages. Myoclonus usually appears 2 or 3 years after the onset of epilepsy, may affect any area of the body, is sensitive to startle, and is absent during sleep. Intellectual deterioration generally follows the appearance of seizures by 2 or 3 years and progresses rapidly to severe dementia. Therapy is symptomatic and is designed to suppress seizures and reduce the severity of myoclonus; some control of myoclonus is achieved with benzodiazepines.

Laboratory findings are normal except for EEG changes; bilaterally synchronous spike-wave discharges of are commonly seen in association with myoclonic jerks. The EEG abnormalities may be found in asymptomatic relatives. The pathologic hallmark of the disease is the presence in the CNS of the bodies first described by Lafora in 1911: round, basophilic, strongly PAS-positive intracellular inclusions that vary in size from dust-like bodies less than 3 nm in diameter to large bodies up to 30 nm in diameter. The medium and large bodies often show a dense core and a lighter periphery. Lafora bodies are seen only in neuronal perikarya and processes and are most numerous in cerebral cortex, substantia nigra, thalamus, globus pallidus, and dentate nucleus.

Ultrastructurally, Lafora bodies are not membrane bound. They consist of two components in various proportions: amorphous, electron-dense granules and irregular filaments. The filaments, which are about 6 nm in diameter, are often branched and frequently continuous with the granular material.

Irregular accumulations of a material similar to that of the Lafora bodies is found in liver, heart, skeletal muscle, skin, and retina, suggesting that Lafora disease is a generalized storage disease. Both histochemical and biochemical criteria indicate that the storage material is a branched polysaccharide composed of glucose (polyglucosan) similar to the amylopectin-like polysaccharide that accumulates in branching enzyme deficiency. The activity of branching enzyme, however, is normal in several tissues, including brain, of patients with Lafora disease. About half of the cases of Lafora disease are due to mutations in the EPM2A gene, which encodes laforin, a member of the dual-specificity protein phosphatase family that additionally contains a glycogen-binding domain. Lafora disease is genetically heterogeneous, and pathogenic mutations have been identified in a second gene, EPM2B, which encodes an E3 ubiquitin ligase called *malin*. Laforin and malin act cooperatively to mediate polyglucosan degradation; the laforin-malin complex also protects against endoplasmic reticulum stress-induced apoptosis. The third gene associated with Lafora body disease is PRDM8, recognized in 2012. This gene encodes PR domain containing protein 8 and is associated with early-onset Lafora disease. The PRDM8 moves laforin and malin to the nucleus; gain-of-function mutations in the gene lead to excessive sequestration of these proteins in the nucleus, and thus, loss of their function in the cytosol.

Metformin showed a neuroprotective effect in a murine model of Lafora disease. A small study in humans identified a few responders, but the role of metformin in human Lafora disease remains unproven.

A clinically distinct form of polyglucosan body disease (APBD) occurs in patients with a complex but stereotyped chronic neurologic disorder characterized by progressive upper and lower motor neuron involvement, sensory loss, sphincter problems, neurogenic bladder, and, in about half of the cases, dementia; there is no myoclonus or epilepsy. Onset is in the fifth or sixth decade of life, and the course ranges from 3 to 20 years. Electrophysiologic studies show axonal neuropathy. In some cases, the clinical picture simulates amyotrophic lateral sclerosis. Throughout the CNS, polyglucosan bodies are present in processes of neurons and astrocytes but not in perikarya. There are also polyglucosan accumulations in peripheral nerve and in other tissues, including liver, heart, and skeletal and smooth muscle. As in debranching enzyme deficiency and Lafora disease, the abnormal polysaccharide in APBD seems to have longer peripheral chains than normal glycogen. Branching enzyme activity was significantly decreased in leukocytes from Israeli patients, and this finding was confirmed in both leukocytes and peripheral nerve specimens from American Ashkenazi Jewish patients. Mutations in the gene encoding the branching enzyme (GBE1) have been found in both Ashkenazi Jewish families with APBD and in non-Jewish patients, confirming that

APBD is a clinical variant of branching deficiency. The observation that APBD is often associated with "mild" GBE1 mutations or even heterozygous mutations may explain the late onset of symptoms. There is no established disease modifying therapy for APBD; a clinical trial of triheptanoin in APBD found no clear evidence of benefit, although the agent was well tolerated.

Another form of polyglucosan is in corpora amylacea, first described by Purkinje in 1837, which accumulate progressively and nonspecifically with age. They are more commonly seen within astrocytic processes in the hippocampus and in subpial and subependymal regions; however, they also occur in intramuscular nerves in patients older than 40 years. The term *Bielschowsky bodies* refers to polyglucosan bodies found in the perikarya of neurons in the globus pallidus of asphyxiated infants with dystonia.

Peroxisomal Diseases: Adrenoleukodystrophy, Zellweger Syndrome, and Refsum Disease

Peroxisomes are ubiquitous cellular organelles that participate in a variety of essential biochemical functions. Peroxisomes are enclosed by a single membrane and contain no DNA, implying that all peroxisomal-associated proteins are encoded by nuclear genes. A complex shuttle system transports peroxisomal enzymes and structural proteins from the cytosolic polyribosomes (where they are made) to the peroxisome. This system involves at least two recognition sequences (peroxisomal targeting sequences) that are embedded in the protein products themselves, and several receptors or transporters; the system is ATP dependent. Peroxisomes participate in both anabolic and catabolic cellular functions, especially in the metabolism of lipids. For example, peroxisomes contain a complete series of enzymes for the β-oxidation of fatty acids. These enzymes are distinct from the mitochondrial enzymes of β-oxidation in both genetic coding and substrate specificity. Because mitochondrial enzymes of β-oxidation cannot metabolize carbon chain lengths greater than 24, the peroxisomal system is required for the degradation of endogenous and exogenous very long-chain fatty acids (VLCFA). The peroxisome is also the site of the initial and rate-limiting steps of the synthesis of plasmalogens, ether-linked lipids that constitute the major portion of the myelin sheath. Other key functions include cholesterol and bile acid biosynthesis, degradation of pipecolic and phytanic acids, and transamination of glyoxylate.

Human diseases caused by disruption of peroxisome function are divided into two broad categories (Table 139.6). The first category is characterized by abnormalities in more than one metabolic pathway, often accompanied by morphologic changes of the peroxisome. The prototype of this class is the Zellweger syndrome, discussed in the following paragraphs. Milder phenotypes in the Zellweger spectrum include neonatal ALD, infantile Refsum disease, and hyperpipecolic acidemia. A second phenotype, distinct from the Zellweger spectrum and termed *rhizomelic chondrodysplasia punctata* (RCDP), is associated with severe growth failure, profound developmental delay, cataracts, rhizomelia (disproportionate length of proximal limbs, such as short limbs of achondroplasia), epiphyseal calcifications, and ichthyosis. Patients with RCDP have decreased plasmalogen levels and elevated phytanic acid, but unlike the Zellweger spectrum, the β-oxidation pathway and VLCFA levels are normal. In recognition of the similar cellular pathophysiology in these phenotypes, *peroxisome biogenesis disorder* (PBD) is now the preferred term for all Zellweger spectrum and RCDP conditions.

TABLE 139.6 Human Genetic Diseases Due to Peroxisomal Dysfunction

Peroxisomal Biogenesis Disorders	Single Peroxisomal Enzyme Disorders
Zellweger syndrome	X-linked adrenoleukodystrophy
Neonatal adrenoleukodystrophy	Oxidase deficiency (pseudoneonatal adrenoleukodystrophy)
Infantile Refsum disease	Bifunctional enzyme deficiency
Hyperpipecolic acidemia	Thiolase deficiency (pseudo-Zellweger)
Rhizomelic chondrodysplasia punctate	DHAP acyl transferase deficiency
	Alky1 DHAP synthase deficiency
	Glutaric aciduria type III (one case only)
	Refsum disease
	Hyperoxaluria type 1
	Acatalasia

Abbreviation: DHAP, dihydroxyacetone phosphate.

The second class of human peroxisomal diseases shows the genetic and biochemical features of single enzyme defects. In addition to X-linked ALD and Refsum disease, discussed later in this chapter, this category includes defects in the β-oxidation pathway of VLCFA, which cause a Zellweger-like phenotype, and defects in plasmalogen synthesis, which result in an RCDP-like phenotype.

Zellweger Spectrum Disorder

Zellweger spectrum disorder has replaced the term *Zellweger syndrome* (cerebrohepatorenal syndrome) and describes a family of disorders, all of which have mutations in a PEX gene. These are autosomal recessive disorders with no ethnic or racial predilection. The PEX genes (pexins) encode gene products that are required for normal peroxisome assembly. Affected newborns are strikingly floppy and inactive and lack neonatal reflexes. The characteristic facies includes a high narrow forehead, round cheeks, flat root of the nose, wide-set eyes with shallow orbits, puffy eyelids, pursed lips, narrow high-arched palate, and small chin. The head circumference is normal, but the fontanels and sutures are wide open. Eye findings include pigmentary retinopathy, retinal arteriolar attenuation, and optic atrophy. The pinnas may be abnormal and posteriorly rotated. Affected infants suck and swallow poorly and often require tube feeding. Some have congenital heart disease, notably patent ductus arteriosus or septal defects. The liver is cirrhotic and either enlarged or shrunken; some children are jaundiced, and some develop splenomegaly and a bleeding diathesis. Cystic dysplasia of the kidneys may be palpable and may cause mild renal failure. Genital anomalies include an enlarged clitoris, hypospadias, and cryptorchidism. Minor skeletal anomalies include contractures of large and small joints, polydactyly, low-set rotated thumbs, and clubfeet; there are also stippled calcifications of the patella and epiphyseal cartilage. The children are apathetic, poorly responsive to environmental stimuli, and limp. Tendon reflexes are absent or hypoactive. Many children have seizures and fail to thrive or develop; most succumb within the first few months of life.

Typical but nonspecific laboratory findings include elevated bilirubin levels, abnormal liver enzymes, elevated serum iron, saturated iron-binding capacity, and transferrin. The CSF protein content may be elevated. The EEG is abnormal, and MRI shows poor myelination, brain atrophy, pachygyria, polymicrogyria, and

neuronal heterotopias. Diffusion-weighted and tensor-diffusion MRIs identify regions of injury in patients with PBD that are not apparent with conventional MRI.

The hallmark of Zellweger spectrum disorders is dysfunction in multiple enzymatic pathways, including the following:

1. Levels of VLCFA—those with 24 or more carbons—are increased in plasma, fibroblasts, and chorionic villus.
2. In plasma and urine, increased content of intermediates of bile acid metabolism includes trihydroxycholestanoic acid and dihydroxycholestanoic acid.
3. Levels of pipecolic and phytanic acids increase.
4. Plasmalogen levels decrease.

Pathologically, the absence of functional peroxisomes in hepatocytes is a pathognomonic feature of Zellweger spectrum disorders and one that helps distinguish it from other PBDs and from single enzyme disorders such as pseudo-Zellweger disease. Membrane proteins may assemble with membrane lipids to form rudimentary "ghosts" of peroxisomes that seem unable to import enzymes. Secondary abnormalities are also seen in mitochondria that show an abnormally dense matrix and distorted cristae.

Therapy for Zellweger spectrum disorders is primarily supportive and limited because of the multisystem impairment already present at birth. Reliable prenatal diagnosis is available by mutation analysis when the genotype has been established in the proband. Living-donor hepatic transplantation has been reported in three patients before the onset of severe complications. One subject succumbed to complications of the procedure, but the other two have shown evidence of clinical and biochemical improvement at 9 months and 17 years follow-up, respectively.

Adrenoleukodystrophy

ALD is an X-linked recessive disorder with variable expressivity; it is well defined genetically, clinically, and pathologically. The ALD gene encodes a member of the ATP-binding cassette transporter class of proteins (ABCD1). The most common phenotype is the childhood cerebral form. Affected boys have normal early development. Behavioral change is the most common initial feature, with abnormal withdrawal, aggression, poor memory, or difficulties in school, ultimately evolving into progressive dementia. Visual loss with optic atrophy reflects demyelination along the entire visual pathway. The outer retina is notably spared. Progressive gait disturbance with pyramidal tract signs is an important feature. Dysphagia and deafness may occur. Seizures are common late in the disease, but are occasionally the first manifestation. Some patients have overt signs of adrenal failure, including fatigue, vomiting, salt craving, and hyperpigmentation that is most prominent in skinfolds. The course is relentlessly progressive. Patients enter a vegetative state and die from adrenal crisis or other causes 1 to 10 years after onset.

Several other clinical phenotypes have been described. Adrenomyeloneuropathy (AMN) is the most common of the variant phenotypes. Typical features are spastic paraparesis, peripheral neuropathy, and adrenal insufficiency, beginning in the second decade. Hypogonadism, impotence, and sphincter disturbance are also seen. Cerebellar dysfunction and dementia have been reported. A similar syndrome is found in about 15% of women who are heterozygous for mutation at the ALD gene. The MRI frequently reveals cortical demyelinating lesions in AMN patients, even in those without signs or symptoms of cortical involvement. Pathologic findings in AMN include demyelination and dying-back changes in the cord, and lamellar cytoplasmic inclusions in brain, adrenal gland, and testis; the findings are similar to those of ALD.

An adolescent cerebral form of ALD is similar to the childhood form but for its onset. In adults, X-linked ALD may present as dementia, schizophrenia, or focal cerebral syndromes such as aphasia, Klüver-Bucy syndrome, or hemianopia; adrenal insufficiency is usually present. Adult ALD includes spastic paraparesis, frontal lobe syndromes, cerebellar dysfunction, or olivopontocerebellar atrophy. Female heterozygotes may be symptomatic with adult ALD. Adrenal insufficiency can be seen without neurologic disorder; ALD should be considered in any boy with unexplained Addison disease. Finally, children and adults with the biochemical defect may be asymptomatic or presymptomatic. Phenotypic heterogeneity is the rule within families with multiple affected individuals; the disparate manifestations are probably the result of modifying genetic loci or environmental factors.

Laboratory evaluation of the patient with ALD reveals elevated CSF protein and posteriorly predominant white matter signal hyperintensity with marginal enhancement. Occasionally, the onset is frontal or cerebellar. The corticotropin stimulation test usually shows adrenal insufficiency, even in the absence of clinical signs. Characteristic inclusions, accumulations of lamellar lipid profiles, may be seen in the brain, adrenal glands, sural nerve biopsy, or testis. The primary finding in the brain is extensive diffuse demyelination, sparing U-fibers in the centrum semiovale and elsewhere. In involved areas of white matter, perivascular infiltration of lymphocytes and plasma cells is prominent.

Diagnosis is suggested by the characteristic clinical findings of neurologic deterioration, demonstration of adrenal hypofunction, and MRI abnormalities. The demonstration of elevated VLCFA levels in plasma and cultured skin fibroblasts without disruption of other peroxisomal functions should be followed by ABCD1 mutation analysis.

Several approaches have been taken to treat ALD. Ideally, cases would be detected at birth, which would allow immediate treatment and genetic counseling for parents. A method for newborn screening is under investigation.

Steroid replacement therapy is given during stressful periods, such as intercurrent illness, or if there is evidence of adrenal insufficiency. Dietary avoidance of VLCFA alone does not lead to biochemical change because of endogenous synthesis. Efforts to lower endogenous synthesis using glycerol trierucate oil and glycerol trioleate oil (Lorenzo oil), in conjunction with dietary restriction, do produce a fall in VLCFA levels, in both affected individuals and female carriers. Unfortunately, this striking biochemical change does not have an equally striking clinical correlate; its use is most likely limited to presymptomatic boys.

Hematopoietic stem cell transplantation has shown benefit in early-stage ALD, in a number of studies since the initial report in 1990, but is accompanied by significant risk, and lesions will typically progress for 12 to 18 months following the procedure until arresting. This delay in response likely reflects gradual replacement of host glial cells by their transplanted counterparts. Several trials of ex vivo gene therapy using lentiviral vectors have shown promising results, which are at least comparable, if not superior, to hematopoietic stem cell transplantation.

Refsum Disease

This autosomal recessive disease (also known as *heredopathia atactica polyneuritiformis*) is unique among the lipidoses because

the stored lipid (phytanic acid) is not synthesized in the body but is exclusively dietary in origin. This has enabled successful therapy by dietary management. Symptoms begin in early childhood in some patients, but may be delayed until the fifth decade in others. Progressive night blindness usually appears in the first or second decade, followed by limb weakness and gait ataxia. Symptoms are progressive, but abrupt exacerbations and gradual remissions may occur with intercurrent illness or pregnancy. There are no seizures, but some patients have psychiatric symptoms. Peripheral neuropathy is manifest by loss of tendon reflexes, weakness and wasting, and distal sensory loss. Ataxia may be seen. A granular pigmentary retinopathy is universally present. Other findings include ichthyosis, nerve deafness (often severe), cataracts, miosis and pupillary asymmetry, pes cavus, and bone deformities with shortening of the metatarsal bones, epiphyseal dysplasia, and, in some, kyphoscoliosis. The CSF protein content is elevated. Nerve conduction velocities are slowed. The ECG changes include conduction abnormalities. Peripheral nerves may feel thickened and, on histologic study, may show hypertrophic interstitial changes and onion-bulb formation. The course is generally progressive with exacerbations and remissions. Peripheral visual fields may ultimately be lost, with resulting telescopic vision. Sudden death may result from cardiac arrhythmia.

The biochemical defect in Refsum disease has been identified as phytanoyl-CoA hydroxylase deficiency; the responsible gene in most cases is PAHX. Several kindreds with typical Refsum disease have lacked PAHX mutations or linkage to chromosome 10; they proved to be heterozygous for mutations in PEX7. The PEX7 gene encodes the receptor for the type 2 peroxisomal targeting signal, whose normal function is essential for phytanoyl-CoA hydroxylase import to peroxisomes. Diagnosis is made by the characteristic clinical picture and elevation of phytanic acid levels in the plasma. Studies in rat brain suggest that phytanic acid exerts direct neurotoxic effects by binding to the inner mitochondrial membrane, impairing mitochondrial ATP supply and membrane permeability.

Therapy limits dietary phytanic acid and its precursor, phytol, a branched-chain fatty alcohol, which is abundantly present in nature as part of the chlorophyll molecule. When dairy products, ruminant fat, and chlorophyll-containing foods are eliminated, plasma phytanic acid levels are reduced and tissue stores are mobilized, with improvement of symptoms. Paradoxically, symptoms may worsen and plasma phytanic acid levels may rise shortly after institution of dietary therapy, especially if patients reduce caloric intake and lose weight. Increased plasma phytanic acid causes anorexia, increased weight loss, and still more severe symptoms. Adequate caloric intake helps prevent weight loss and abrupt fat mobilization. Plasmapheresis helps to prevent or treat exacerbations. Induction of phytanic acid ω-oxidation might be helpful. Cochlear implantation has been successful in a few patients with Refsum disease. Cataract surgery improves visual outcomes in patients with Refsum disease, and other disorders in which both cataracts and retinal dystrophy occur, but is associated with an increased risk of complications. Liver transplantation has led to biochemical improvement, but no clinical benefit, and is not currently recommended.

Another rare peroxisomal phenotype can be confused with Refsum disease. Patients with α-methylacyl-CoA racemase deficiency may have retinopathy and peripheral neuropathy plus a variety of cerebral findings, including seizures, progressive cognitive decline, and relapsing encephalopathy.

Chromosomal Disorders and Disorders of DNA 140

Marc C. Patterson

KEY POINTS

1. Chromosomal disorders are associated with a substantial number of neurodevelopmental diseases; these are often, but not invariably, associated with abnormal development of other organ systems.
2. They range from addition or subtraction of entire chromosomes (aneuploidy) to copy number variations associated with microdeletions and duplications.
3. In some cases, the DNA sequence is intact, but gene expression has been silenced by abnormal methylation (imprinting).
4. Disorders of DNA maintenance, transcription, and translation are commonly associated with varying combinations of premature aging, neurodegeneration, light sensitivity, immunodeficiency, and susceptibility to malignancy.

INTRODUCTION

Rearrangements of the human genome, ranging from grossly disordered chromosome number to submicroscopic variations in copy numbers can profoundly affect development and function of the nervous system. Likewise, defects in the machinery that maintain the integrity and duplication fidelity of DNA lead to a family of rare disorders characterized by varying combinations of neurodegeneration, premature aging, light sensitivity, immunodeficiency, and susceptibility to malignancy.

CHROMOSOMAL DISORDERS

Human chromosomal anomalies are manifested as change in the total number of chromosomes, structural rearrangements, imprinting abnormalities, or variations in copy number. Examples of abnormal chromosome number (ie, aneuploidy) are sex-chromosomal aneuploidy, such as 45,X (Turner syndrome), and autosomal aneuploidy, such as 47,XX +21 (trisomy 21, Down syndrome). Structural abnormalities include regional deletions or insertions, segmental translocations (ie, reciprocal or Robertsonian) or inversions (ie, pericentric or paracentric), duplications, and ring chromosomes. There are many chromosomal syndromes, which result primarily from these numeric or segmental anomalies, producing a functional change of gene dosage; gene imprinting is also recognized as a critical modifier of expression. The most common manifestation of chromosomal anomalies is intellectual disability. Congenital malformations occur with variable frequency and differences in severity. In the sex-chromosome disorders, infertility is the most common feature. In Table **140.1**, I summarize the features of several classic chromosome disorders as examples: trisomy 21, Prader-Willi syndrome (PWS), Angelman syndrome (AS), and a common idiopathic intellectual disability syndrome caused by subtelomeric anomalies of chromosomes. A variety of mechanisms underlie these disorders. Trisomy 21 results from chromosomal nondisjunction (maternal 80%, paternal 20%), an age-related phenomenon in most cases, and unbalanced translocation in the remainder. The PWS and AS result from loss of paternally or maternally imprinted alleles in the same chromosomal

TABLE 140.1 Common Chromosomal Disorders

Genetic Abnormality/Eponym	Key Clinical Features	Diagnosis
Trisomy 21; chromosome 14/21 translocation; Down syndrome	Intellectual disability, hypotonia, atlantoaxial instability, short stature. Characteristic round facies with epicanthal folds. Early-onset dementia; congenital heart disease, increased risk of leukemia	Chromosome analysis
Prader-Willi syndrome; 15q11-13 deletion	Neonatal hypotonia and failure to thrive, followed by uncontrolled appetite with obesity (hypothalamic dysfunction); characteristic facial features, intellectual disability and behavior (obsessiveness, mood swings, skin picking)	DNA methylation analysis (loss of paternal allele at *SNRPN* locus: includes 15q11-13 deletion, uniparental disomy and imprinting defects—detects 99% of cases)
Angelman syndrome; 15q11-13 deletion	Characteristic facies, microbrachycephaly, protruding tongue, jerky limb movements (features may not be apparent until after 1 y); developmental delays and intellectual disability	DNA methylation analysis (loss of maternal allele: includes 15q11-13 deletion, uniparental disomy and imprinting defects—78% of cases); UBE3A mutation analysis (11% of cases); chromosome analysis (translocations, inversions—1% of cases); no diagnostic test findings—10% of cases
22q11 deletion syndrome (CATCH-22; DiGeorge; velocardiofacial syndrome)	Cardiac malformations, facial clefts, other cranial and brachial arch anomalies, dysmorphism, intellectual disability and psychiatric disorders (schizophrenia, OCD, ASD, and ADHD)	FISH, MLPA, chromosomal microarray (detects 95+% of cases)

Abbreviations: ADHD, attention deficit hyperactivity disorder; FISH, fluorescent in situ hybridization; MLPA, multiplex ligation-dependent probe amplification; OCD, obsessive-compulsive disorder; ASD, autism spectrum disorder.

region (15 q11-13); such loss may reflect abnormal imprinting (methylation—see in the following text), chromosomal deletion, translocation or inversion, or point mutations in a specific gene (UBE3A for AS). CATCH-22 is a deletion syndrome—the manifestations are at least in part a reflection of the amount of genetic material that is lost.

Genomic Imprinting

Genomic imprinting is an epigenetic phenomenon that permits non-Mendelian inheritance in the mammalian genome. Several autosomal genes are inherited, in a silent state, on one parental allele, and in an active state on the other parental allele. This parent-of-origin–specific gene expression is called *genomic imprinting*. The diseases that arise from these genes are mostly caused by mutation of the active allele, duplication of the nonactive allele, or imprinting errors resulting in silencing of the active allele. Over 20 imprinted genes have now been identified in the mouse genome; many of them have human homologs. For example, the *IGF-2* gene is paternally active, and only when the gene defect is inherited from the father do the offspring express the dwarfing phenotype. In PWS and AS, deletions in the PWS critical region on the paternal chromosome, or maternal uniparental disomy, result in silencing the paternally active allele and the PWS phenotype, whereas deletion of the AS critical region on the maternal chromosome, or paternal uniparental disomy, results in the silencing of the maternal allele and the AS phenotype.

The molecular mechanism of genomic imprinting is incompletely understood. The isolation of a *cis*-acting imprinting center, located upstream to the promoter region of the *SNRPN* gene, has helped us understand the molecular basis of genomic imprinting. Deletions or mutations in this imprinting center have been shown to associate with PWS or AS, depending on the origin of parental germ lines. It is postulated that the imprinting center confers a male or female imprint by use of an imprinting switch during gametogenesis. In the female germ line, the imprinting switch is needed to reset the male chromosome from the maternal grandfather, to confer the characteristics of a female chromosome. In the male germ line, the same process is needed to reset the female chromosome from the paternal grandmother to confer the characteristics of a male chromosome. This epigenetic mark is thought to be achieved by DNA methylation. In the case of PWS, the inactive allele on the maternal chromosome is hypermethylated, which suppresses gene transcription. The hypermethylated cytosine residues on the DNA sequences may repel the transcription factors needed for the activation of gene transcription. In other imprinted genes such as the insulin-like growth factor 2 (IGF-2) receptor, DNA methylation is associated with the active allele on the maternal chromosome. Therefore, other factors in addition to DNA methylation may be involved in genomic imprinting.

Autism Spectrum Disorder and Genomic Imprinting

Autism is a neurodevelopmental disorder characterized by language and social impairments and prominent repetitive, stereotypic behaviors. Interstitial duplication of maternal chromosome 15q11-13 region is one of the more common chromosomal anomalies in autism. Clinically, there are some phenotypic overlaps between autism spectrum disorders and PWS. Interestingly, among the children with PWS, those who express two maternally imprinted alleles are twice more likely to have autism spectrum disorder than those with PWS caused by deletion of paternally imprinted alleles. The identification of mutations in the methyl CpG-binding protein 2 gene as the major cause of Rett syndrome suggested that DNA methylation (and hence genomic imprinting) may play important roles in other neurodevelopment disorders.

Subtle chromosomal anomalies such as subtelomeric and submicroscopic deletion or duplication frequently give rise to neurologic phenotypes, without necessarily causing somatic manifestations. Techniques using subtelomeric probes led the way in improving cytogenetic diagnosis but have been largely supplanted by array comparative genomic hybridization (CGH) in the investigation of idiopathic intellectual disability and cancers.

Intellectual Disability Associated With Subtelomeric Chromosomal Deletion

Telomeres are the chromosome ends that contain complex DNA protein structures. The DNA sequence is a repetitive-hexanucleotide motif, TTAGGG, ranging from 2 to 15 kb in length. This repetitive sequence and its specific DNA-binding proteins form a cap structure at the chromosome ends. This cap structure enables cells to distinguish chromosome ends, prevents fusion or degradation of chromosomes, and facilitates chromosomal segregations during cellular divisions. A reverse transcriptase named telomerase recognizes this terminal repetitive-DNA sequence and works to maintain the chromosomal integrity by adding telomeric DNA onto chromosome ends, when a lagging strand is created during replication. Anomalies of these DNA protein structures change the chromosomal length. Shortening of telomeric length is seen in normal aging of somatic cells, whereas unchecked telomerase activation results in chromosomal fusion, as is often seen in cancer cells.

Intellectual disability is a common developmental disorder. The etiology of about 30% to 40% of moderate-to-severe intellectual disability (IQ < 50) remains unknown, despite extensive diagnostic testing, and these patients have a normal karyotype using routine- or high-resolution chromosomal-banding techniques.

Since the early 1990s, researchers have developed DNA probes to detect subtle subtelomeric-chromosomal anomalies in humans. At least 5% of children with idiopathic intellectual disability harbor subtelomeric-chromosomal rearrangements, detected by a set of subtelomeric probes in different fluorescent in situ hybridization studies. These rearrangements include subtelomeric deletions, duplications, or derivative chromosomes resulting in partial monosomy–trisomy states. The positive detection rate increases when screening criteria include severe intellectual disability, positive family history of intellectual disability, and at least one physical dysmorphism. In selected cases, fluorescent in situ hybridization study remains a useful tool for identifying the etiology of the disorders of patients with idiopathic intellectual disability and is often used to refine or confirm findings from chromosomal microarray studies.

Chromosomal Microarray

The general term *chromosomal microarray* refers to at least two different techniques, which detect copy number variations using microchips.

Single nucleotide polymorphism arrays rely on recognition of changes of single nucleotides, specifically those that would be

predicted to alter the amino acid sequence of the protein encoded by that stretch of DNA. In addition, they have the potential to detect uniparental disomy, which is important in a number of chromosomal disorders, including PWS and AS. Single nucleotide polymorphism arrays have been recommended as an efficient screening test in populations with intellectual disability, with a diagnostic yield greater than 10% in one study.

Array Comparative Genomic Hybridization

Chromosomal disorders arising from segmental deletion or duplication contribute to variations of copy numbers of DNA fragments. These fragments are often not visualized by current high-resolution chromosomal banding. This submicroscopic genomic copy number variation is thought to be the most common cause of idiopathic developmental delay, including intellectual disability. In CGH, the patient's DNA is hybridized to arrayed genomic DNA targets (genomic clones or oligonucleotides) on a glass slide or gene chip. The signal intensities of each hybridized genomic target are compared with those of the control standards (or the parents). Variation of copy numbers can be readily detected. This genetic diagnostic tool has led to the identification of an evergrowing family of novel microdeletion syndromes. The repetitive observation of microscopic chromosomal anomalies and their correlation with certain clinical phenotypes is likely to identify the genetic causes of many idiopathic neurodevelopmental disorders whose cause is currently unknown. Investigators have reported relatively high yields of CGH in cohorts with intellectual disability and autism, in both children and adults.

DISORDERS OF DNA MAINTENANCE, TRANSCRIPTION, AND TRANSLATION

Except for components of the respiratory chain encoded by mitochondrial DNA, the DNA of the nucleus is responsible for the production of the molecules essential to the cellular economy. Disorders that impair the maintenance of the integrity of DNA, or its timely and accurate transcription and translation, frequently lead to neurodegeneration, impaired growth, premature aging, and a propensity to develop malignancies. The brain is particularly vulnerable to these disorders because cerebral neurons are, for practical purposes, irreplaceable, and their high metabolic rate mandates high levels of oxygen consumption; both of these factors render the central nervous system (CNS) more susceptible to damage by reactive oxygen species and other metabolites than less richly endowed tissues.

This section provides an introduction to the processes involved and the rare diseases resulting from derangement of these controls. It is likely that the number of these disorders will continue to grow in parallel with the relevant basic science. Neurologists in the 21st century must have a firm grasp of the essential principles to diagnose and manage people affected by these diseases.

DNA Maintenance and Transcription

The DNA is subject to errors in its duplication during cell division and during the process of repair following exposure to a variety of mutagens (environmental, toxic, and therapeutic). The elaborate machinery includes helicases that unwind the strands of DNA in preparation for transcription into RNA,.RNA polymerase, which directs the formation of messenger RNA (mRNA) on the DNA template, and DNA polymerase, which catalyzes the duplication of DNA. The process is fine-tuned by a large family of transcription factors; investigators are constantly adding to their number. This process is highly dependent on sites of replication origin, which change during development and in the face of disease.

A complex system has evolved to correct errors in nucleic acid duplication. When single bases are incorrectly inserted into the new DNA molecules, they are removed by the process of base excision repair, mediated by specific DNA glycolyases and endonucleases and DNA polymerases and ligases. Longer segments of 25 to 32 bases are frequently damaged by exposure to ultraviolet radiation and are removed by nucleotide excision repair, which requires its own family of proteins. Breaks of double-stranded DNA activate a mechanism that requires the participation of DNA protein kinase and recombination proteins. The processes are even more complex than is implied by this brief overview because many of the involved proteins play multiple, mutually modifying roles in repair and transcription.

Precursor-mRNA (pre-mRNA) is transcribed from the genomic DNA template and includes the sequences of both expressed sequences (exons) and intervening sequences (introns). Introns are removed from pre-mRNA by RNA splicing to produce the mRNA used in translation of the message into protein. This process requires the participation of five additional RNA molecules (small nuclear RNAs) and more than 50 proteins. The small nuclear RNAs are added to multiprotein complexes known as *spliceosomes*. The steps involved in pre-mRNA processing into mRNA occur in the nucleus and conclude with export of the mRNA to the cytoplasm via the nuclear pore complex.

DNA Translation and Modification

Translation of mRNA requires intact ribosomal function, factors to control the initiation and duration of translation, and machinery to modify the nascent polypeptide chains by the addition of smaller molecules, particularly oligosaccharides. This modification amplifies the ability of the organism to respond to changing needs at different stages of development (such as differing proportions of enzyme or structural protein isoforms) or in response to external stimuli (as in the modification of T-cell receptor populations and other elements of the immune system to target invading microorganisms). The most important such processes are *N*- and *O*-linked glycosylation.

Cell Cycle Control

The activity of the systems responsible for DNA transcription, maintenance, and translation is related to the phase of the cell cycle, which is regulated by a highly conserved family of protein kinases known as *cyclin-dependent kinases*. Cyclin-dependent kinases are themselves regulated by inhibitory phosphorylation (Wee1), dephosphorylation (Cdc25), the binding of inhibitor proteins (CKIs), and through cyclical proteolysis (ubiquitin ligases and activators—SCF, APC, Cdc20, Hct1) and gene regulatory proteins (E2F, p53).

Specific Disorders

Table 140.2 summarizes selected monogenic DNA disorders. The categorization of specific disorders in one category is an arbitrary oversimplification because the gene products have multiple actions in many cases.

TABLE 140.2 Selected Disorders of DNA Synthesis, Maintenance, Transcription, and Translation

Disorder	Inheritance	Gene and Protein	Mechanism (Known or Putative)	Specific Features
DNA Maintenance and Transcription				
Cockayne syndrome type 1 (CSA) MIM 216400	AR	*CSA* ERCC8	CSA/ERCC8 interacts with p44, CSB, and TFIIH. Mutations thus lead to RNA polymerase II dysfunction and impaired nucleotide excision repair.	Intellectual disability, accelerated aging, pigmentary retinal degeneration, optic atrophy, deafness, marble epiphyses, photosensitivity, and basal ganglia/cerebellar calcification
COFS MIM 214150	AR	*CSB* ERCC6	Abnormal nucleotide excision repair resulting from disturbed RNA polymerase I–TFIIH interaction within the CSBIP/150 complex, of which CSB/ERCC6 is a component	Microcephaly, microphthalmia, cataracts, dysmorphism, failure to thrive, recurrent pneumonias, axial hypotonia, appendicular hypertonia, hyperreflexia, and progressive contractures; calcifications in the periventricular frontal white matter and basal ganglia
Progeria MIM 176670	AR	*LMNA* Lamin A	Lamins are structural components of the nuclear membrane. Mutations in *LMNA* are associated with both defective nuclear mechanics and impaired transcriptional activation.	Postnatal onset of short stature, failure to thrive and accelerated aging, loss of scalp hair, subcutaneous fat, joint stiffness and early atherosclerosis leading to strokes and myocardial infarcts, and premature death. Elevated prothrombin time, platelets, phosphorous; conductive hearing loss is also reported. Cognition is spared.
XP (de Sanctis-Cacchione syndrome—most commonly complementation group D—XPD) MIM 278730	AR	*ERCC2* ERCC2	Abnormal nucleotide excision repair: *XPD* (*ERCC2*) interacts with the p44 subunit of TFIIH stimulating 5′-3′ helicase activity. Mutations in the *XPD* prevent the interaction with p44, leading to decreased *XPD* helicase activity.	Intellectual disability, short stature, facial freckling, spasticity, hypogonadism, and olivopontocerebellar atrophy
Trichothiodystrophy (TTD 1) MIM 601675	AR	*ERCC2* ERCC2	As for XP; TFIIH also stabilizes thyroid hormone receptors in TTD mouse brain.	Intellectual disability, hair shaft abnormalities, ichthyosis, immature sexual development, short stature, and facial dysmorphism
Rett syndrome MIM 312750	X linked	*MECP2* MeCP2	Regulation of gene expression, chromatin composition, and chromosomal architecture through binding to methylated DNA. The MeCP2 is expressed ubiquitously by neurons; levels of MeCP2 expression increase during neuronal differentiation and remain at high levels in the adult brain.	Classic phenotype restricted to females; normal development for first 6 mo, followed by acquired microcephaly, loss of hand skills and replacement by stereotypies, regression of skills, seizures, spasticity, and scoliosis
Spinal muscular atrophy 1, 2, and 3 MIM 253300, 253550, 253400	AR	*SMN1* SMN	*SMN1* is a key component of the spliceosome complex; selective vulnerability of anterior horn cells is not yet understood.	Loss of anterior horn cells (and neurons of brainstem and thalami in severe cases)

(table continues on page 1414)

TABLE 140.2 Selected Disorders of DNA Synthesis, Maintenance, Transcription, and Translation *(continued)*

Disorder	Inheritance	Gene and Protein	Mechanism (Known or Putative)	Specific Features
DNA Translation and Translational Modification				
CACH, Cree leukoencephalopathy, ovarioleukodystrophy **MIM 603896**	AR	*EIF2B1* *EIF2B2* *EIF2B3* *EIF2B4* *EIF2B5* eIF2B	Translation initiation factor 2B catalyzes exchange of GDP for GTP, an essential stage in recycling of eIF2; GEF activity. Mutations in any of the five genes coding for subunits of eIF2B cause loss of normal downregulation of protein translation under stress, resulting in protein denaturation and accumulation of aggregates producing cellular toxicity.	Slowly progressive ataxia with diffuse loss of white matter; episodes of coma with fever and motor impairment with minor trauma
CDG-1a **MIM 212065**	AR	*PMM2* PMM2	PMM2 is one of a family of enzymes catalyzing the assembly of the LLO precursor that is attached to the nascent polypeptide chain during cotranslational modification by *N*-linked glycosylation.	Intellectual disability, short stature, progressive ataxia, peripheral neuropathy, stroke-like episodes, seizures, immune dysfunction, intermittent hepatic failure, coagulopathies
Cell Cycle Regulation				
Angelman syndrome **MIM 105830**	Multiple mechanisms, including maternal deletion of 15q11-13, paternal uniparental disomy, imprinting defects, and point mutations or small *UBE3A* intragenic deletions. Some patients have *MECP2* mutations.	*UBE3A* Ubiquitin-protein ligase E3A	The *UBE3A* gene encodes sense and antisense RNA transcripts in the brain with neuron-specific imprinting of *UBE3A* in primary brain cell cultures. The maternal *UBE3A* allele is preferentially expressed in the neuronal nucleus and at synapses; absence of this allele is associated with abnormal dendritic spine morphology.	Psychomotor retardation, ataxia, hypotonia, epilepsy, absence of speech, large mandible, and tongue thrusting; optic atrophy and albinism in some
Ataxia-telangiectasia **MIM 208900**	AR	*ATM* ATM	The ATM protein is a PI3K that phosphorylates key substrates involved in DNA repair and/or cell cycle control.	Progressive ataxia, choreoathetosis, anterior horn cell loss, immune deficiency, scleral telangiectasia
Seckel syndrome 1 **MIM 210600**	AR	*ATR* ATR *CEP152* Centrosomal protein 152	ATR is a PI3K involved in cell cycle progression, DNA recombination, and the detection of DNA damage; *CEP152* regulates genomic integrity and cellular response to DNA damage.	Short stature, dysmorphism ("bird-headed dwarf"), congenital microcephaly, intellectual disability; no immune deficiency or cancers

Abbreviations: AR, autosomal recessive; ATM, ataxia-telangiectasia mutated; ATR, ataxia-telangiectasia and Rad3-related; CACH, childhood ataxia with central nervous system hypomyelination; CDG-1a, congenital disorder of glycosylation 1a; COFS, cerebro-oculo-facio-skeletal syndrome; CSA, Cockayne syndrome group A; CSB, Cockayne syndrome group B; CSBIP, CSB IP/150, CSB immunoprecipitated fraction; eIF2, eukaryotic initiation factor 2; eIF2B, eukaryotic translation initiation factor 2B; ERCC2, excision repair cross-complementing rodent repair deficiency 2; ERCC6, excision repair cross-complementing rodent repair deficiency 6; ERCC8, excision repair cross-complementing rodent repair deficiency 8; GEF, guanine nucleotide exchange factor; LLO, lipid-linked oligosaccharide; MeCP2, methyl CpG-binding protein 2; PI3K, phosphatidylinositol 3-kinase; PMM2, phosphomannomutase 2; TFIIH, transcription factor II H; TTD, trichothiodystrophy; XP, xeroderma pigmentosum.

The Floppy Infant 141

Maryam Oskoui, Laurent Servais, and Darryl C. De Vivo

KEY POINTS

1. Central causes of congenital hypotonia are more common than peripheral causes.
2. Polyhydramnios, fetal akinesia, and perinatal malpresentation are frequently recognized in infants with neuromuscular disorders.
3. Hypoxic-ischemic encephalopathy is the most common cause of hypotonia in the newborn period.
4. Acute-onset constipation and cranial nerve involvement should suggest infantile botulism.
5. The triad of infantile hypotonia, areflexia, and tongue fasciculations should suggest 5q spinal muscular atrophy caused by homozygous *SMN1* deletions, a medical emergency demanding immediate disease-modifying therapy to achieve optimal outcome.
6. Infants of mothers with myasthenia gravis or myotonic dystrophy should be monitored for neuromuscular signs in the newborn period.
7. Early-onset neuropathies are more often hypomyelinating than axonal and can be associated with central nervous system involvement.
8. The presence in infancy of cardiomyopathy and elevated creatine kinase should suggest Pompe disease and early treatment with enzyme replacement therapy.

INTRODUCTION

Tone opposes gravity and maintains postural attitude. The term *hypotonia* refers to a state of low muscle tone. When held by an examiner in prone position in horizontal suspension, a full-term infant maintains a straight back and neck with flexed limbs. A hypotonic infant will drape over the examiner's hand with limbs and head hanging limply, thus the origin of the term *floppy infant*. Low neck tone can be observed when pulling the infant to a sitting position if it offers little or no resistance and the head remains in extension or falls forward once seated upright. In vertical suspension, the hypotonic infant's torso slips through the examiner's hands because of low tone in shoulder girdle muscles instead of adduction of the arms and fixing at the shoulders. Decreased limb recoil and a scarf sign are observed with appendicular hypotonia in addition to diminished resistance to passive limb movement when examined. The floppy infant seems to be weak, but the examiner may find it difficult to distinguish between true weakness and apparent weakness due to hypotonia and/or hyperlaxity.

The hypotonic infant represents a diagnostic challenge with a seemingly limitless differential diagnosis. Clues on history and examination can help narrow the list of possible etiologies (Fig. 141.1). Family history may reveal an inherited risk for hypercoagulability (including prior maternal spontaneous abortions), immune-mediated conditions, genetic syndromes (premature death may suggest a metabolic syndrome), neuropathies, myasthenia gravis, or myopathies/muscular dystrophies (developmental delay and weakness). Maternal neuromuscular disorders such as myotonic dystrophy or myasthenia gravis may have been previously undiagnosed with milder symptoms, and a high clinical suspicion is needed. The pregnancy history should highlight possible decreased fetal movements (akinesia), polyhydramnios (decreased fetal swallowing), in utero toxin exposure (alcohol, narcotics, antiepileptic drugs), and intrauterine infections (herpes simplex, cytomegalovirus, toxoplasmosis, rubella). The perinatal history includes gestational age (prematurity), difficult delivery (sentinel event, perinatal depression, or shoulder dystocia), and breech presentation. It should also be noted whether the infant had low tone, limb contractures, difficulty breathing, poor suck, feeding difficulties, or a weak cry at birth. Potential exposures to *Clostridium botulinum* (via honey, corn syrup or home-canned goods consumption, or dirt) should be considered. The temporal pattern of the hypotonia itself is informative, whether it is present prenatally, at birth, or after birth and whether it improves, worsens, or transforms to spasticity over time.

The aforementioned history will complement a careful neurologic exam designed to identify (1) unique dysmorphic features; (2) a highly arched palate or tenting of the mouth (suggestive of congenital tongue weakness); (3) respiratory distress with paradoxical breathing; (4) cardiomyopathy (seen in carnitine deficiency, fatty acid oxidation disorders); (5) organomegaly (seen in acid maltase deficiency, Zellweger syndrome, and other storage disorders); (6) genitourinary abnormalities such as hypogonadism and hypospadias (Prader-Willi syndrome, Smith-Lemli-Opitz syndrome); (7) skin changes (birthmarks seen in neurocutaneous syndromes, doughy quality); (8) musculoskeletal abnormalities (congenital scoliosis, kyphosis, contractures seen in arthrogryposis, hip dysplasia, torticollis, hyperextensibility of joints); (9) level of alertness (encephalopathy); (10) quality of cry; (11) cranial nerve dysfunction such as facial weakness, ptosis, limited extraocular movements, tongue fasciculations, tongue atrophy, strength of suck; (12) focal or diffuse weakness; (13) evidence of hypertonicity (increased jitteriness and rigidity of the limbs) or hypotonicity (frog-legged posture while supine, lack of spontaneous movement, scarf sign, tendency to keep the trunk flexed while held in horizontal suspension, slip through); and (14) tendon reflex responses. The pertinent findings on examination in conjunction with a thorough history will guide the clinician to whether the infant's presentation is related to a nonneurologic (metabolic, systemic or genetic syndrome)

FIGURE 141.1 Differential diagnosis for hypotonia in infants. [a]May be associated with pathognomonic dysmorphic features. [b]Muscle ultrasound (MUS) is not diagnostic for neuromuscular junction dysfunction but can visualize fasciculations and fibrofatty replacement in muscle either due to myopathy, neuropathy, or motor neuron disease. [c]May also present with seizures. Abbreviations: AADC, aromatic l-amino acid decarboxylase deficiency; ADG, α-dystroglycanopathy; AGP, arthrogryposis; CDG, congenital disorder of glycosylation; CFTD, congenital fiber-type disproportion; CHN, congenital hypomyelinating neuropathy; CM, congenital myopathy; CMG, congenital myasthenia gravis; CMT, Charcot-Marie-Tooth; CNM, centronuclear myopathy; CMTX, Charcot-Marie-Tooth disease type X; DM1, myotonic dystrophy; DNM2, dynamin 2 gene; DSD, Dejerine-Sottas disease; EMG, electromyography; GAN, giant axonal neuropathy; GDAP1, ganglioside induced differentiation associated protein 1; INAD, infantile neuroaxonal dystrophy; LAMA2, laminin α_2 gene; MFN2, mitofusin 2 gene; MRI, magnetic resonance imaging; MTM1, myotubularin 1 gene; MYH3, myosin heavy chain 3 gene; MYH8, myosin heavy chain 8 gene; NCS, nerve conduction studies; NMJ, neuromuscular junction; NT, neurotransmitter; PWS, Prader-Willi syndrome; RYR1, ryanodine receptor 1 gene; SEPN1, selenoprotein 1 gene; SMA, spinal muscular atrophy; SMARD, spinal muscular atrophy and respiratory distress; SMARD1, spinal muscular atrophy and respiratory distress type 1; SPEG, striated muscle preferentially expressed protein kinase; TMG, transient myasthenia gravis; TRPV4, transient receptor potential cation channel, subfamily V, member 4; TTN, titin gene; UMN, upper motor neuron.

or neurologic etiology that may be primarily central (brain and spinal cord), peripheral (anterior horn cell, peripheral nerve, neuromuscular junction, or muscle), or both.

CENTRAL HYPOTONIA

Central hypotonia is due to lesions above the anterior horn cells of the spinal cord. Central hypotonia is often symmetric and affects the upper and lower limbs equally as well as the trunk. It may also present with additional features of central nervous system (CNS) involvement such as early developmental impairment, seizures, encephalopathy, or brisk tendon reflexes.

Vascular Causes

Hypoxic-ischemic encephalopathy develops in the setting of perinatal hypoxia and is by far the most common cause of hypotonia seen in newborns. The initial presentation of hypoxic-ischemic encephalopathy in the newborn period may be hypotonia and hyporeflexia in addition to seizures, decreased level of alertness, and irritability. There may be a history of a sentinel event, and signs of perinatal distress may be observed. Over time, the initial presentation of hypotonia usually gives way to hypertonia with increased tendon reflexes and spasticity (refer to Chapter 137). Other vascular etiologies include intraventricular hemorrhage seen in premature newborns (see Chapter 137) and ischemic or hemorrhagic stroke (see Chapter 149). Investigations for these etiologies include brain imaging (magnetic resonance imaging [MRI]) and electroencephalography, and examination of the placental pathology can provide further etiologic clues.

Structural Causes

Neuronal migration disorders include holoprosencephaly, anencephaly, lissencephaly, pachygyria, polymicrogyria, and/or heterotopias (refer to Chapter 138). Microcephaly, dysmorphic features, and seizures can be observed. It should be noted that neuronal migration disorders might be part of a larger syndrome that can also present with peripheral hypotonia, for example, congenital muscular dystrophies such as Fukuyama congenital muscular dystrophy, Walker-Warburg syndrome, or muscle-eye-brain disease (refer to Chapter 147). Several forms of cerebral palsy (CP) can present with truncal hypotonia in infancy, such as ataxic or dyskinetic subtypes. The CP is an umbrella term including a heterogenous group of conditions involving nonprogressive central motor impairment due to abnormalities of the developing fetal or infant brain. Cerebral maldevelopment, deep gray matter or cerebellar abnormalities, and nonspecific neuroimaging can be seen in CP. Intracranial neoplasms presenting in infancy should also be considered in the context of macrocephaly, vomiting, or cranial nerve involvement (refer to Chapter 150). Investigations to consider include brain imaging, electroencephalography in the context of encephalopathy or seizures, creatine kinase if a congenital muscular dystrophy is suspected, ophthalmologic evaluation, and genetic testing such as chromosomal microarray and targeted gene sequencing.

Metabolic Causes

Inborn errors of metabolism include toxic accumulation of metabolites such as aminoacidopathies, organic acidurias and urea cycle defects, disorders of energy metabolism such as fatty acid oxidation defects and other mitochondrial disorders, glycogen storage disorders, and disorders affecting intracellular processing of small molecules such as peroxisomal disorders including Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease (refer to Chapter 139). Some inborn errors of metabolism may also cause peripheral neuropathy. Other clinical features can include lethargy, apnea or tachypnea, poor feeding, seizures, vomiting, organomegaly, or ambiguous genitalia. The temporal pattern of symptoms such as cyclical symptoms, worsening with systemic stress, or development of symptoms with the introduction of feedings can lend further clues. Investigations to consider when a metabolic etiology is considered would include serum glucose, electrolytes, plasma amino acids, urine organic acids, acylcarnitines, ammonia, liver function, thyroid profile, lactate, pyruvate, calcium, magnesium, uric acid, isoimmune electrophoresis for transferrin, carnitine profile, very long chain fatty acids, and cerebrospinal fluid (CSF) studies for glucose, protein, amino acids, lactate, pyruvate, neurotransmitters, pterins, and 5-methyltetrahydrofolate.

Systemic Causes

Systemic causes include infections, electrolyte or hormonal imbalance, and toxin exposure. Congenital infections include toxoplasmosis, *Treponema pallidum*, rubella, cytomegalovirus, herpesvirus, hepatitis B and C viruses, human immunodeficiency virus, varicella, and parvovirus B19. These may present with hypotonia in addition to other features of intracranial calcifications or cysts, abnormal liver function, skin rash, hearing loss, encephalopathy, seizures, and/or retinitis or optic nerve atrophy. Over time, the exam can evolve to spasticity and increased tendon reflexes. Acute sepsis and CNS infection in infants can also present with hypotonia, hypo- or hyperthermia, and encephalopathy. Infants of diabetic mothers, premature newborns, or those born with intrauterine growth restriction are at higher risk for hypoglycemia at birth. Congenital hypothyroidism is now included in most newborn screening programs. Intrauterine exposure to drugs such as lamotrigine, lithium, narcotics, and benzodiazepines has been associated with hypotonia. Antepartum or peripartum maternal exposure to high levels of magnesium sulfate for the treatment of eclampsia and prevention of cerebral palsy has also been associated with congenital hypotonia. Investigations to consider include blood, urine, and CSF bacterial and viral studies; urine and blood toxin screens; and serum glucose, electrolytes, and thyroid-stimulating hormone level.

Chromosomal Disorders

Genetic syndromes that most commonly present with hypotonia include Down syndrome (distinct facial features and higher risk of associated cardiac anomalies and duodenal atresia), Prader-Willi syndrome (distinctive facial features, genital hypoplasia, initial failure to thrive followed by hyperphagia, and obesity after age 1 year), fragile X syndrome, Cohen syndrome, trisomy 18, 1p36 deletion, 22q13 deletion syndrome, 22q11.2 deletion syndrome, DiGeorge/velocardiofacial syndrome, Williams syndrome, trisomy 13, Smith-Magenis syndrome, Sotos syndrome (macrocephaly), Lowe syndrome, Smith-Lemli-Opitz syndrome, Wolf-Hirschhorn syndrome, Kabuki syndrome, Cri-du-chat syndrome (refer to Chapter 140). Investigations include specific

genetic studies such as FMR1, array comparative genomic hybridization, 7-dehydrocholesterol, and cardiac evaluation.

Spinal Cord

For discussion of spinal dysraphism/spina bifida, refer to Chapter 138. Spinal cord injury may be secondary to intrauterine mispositioning or trauma/severe asphyxia during birth (via hypoperfusion between the anterior spinal artery and paired spinal arteries) that subsequently damages the lower motor neurons of the spinal cord. Autopsy studies of fatally asphyxiated neonates demonstrate prominent, ischemic necrosis of anterior spinal cord gray matter. Infants with spinal cord injury often present with hypotonia, weakness, and absent tendon reflexes only in the regions distal to the site of injury. Ultrasound/MRI of the spine also may be used to identify cord ischemia or spinal dysraphism.

PERIPHERAL HYPOTONIA

Peripheral hypotonia refers to disorders of the motor unit (anterior horn cell, peripheral nerve, neuromuscular junction, and muscle). The distribution of the muscle weakness can help with diagnosing its etiology. Investigations to identify the underlying etiology can include electromyography and nerve conduction studies (EMG/NCS), serum creatine kinase, muscle imaging, genetic testing and muscle or nerve biopsy.

Anterior Horn Cell Disorders

The quintessential anterior horn cell disease in infancy is 5q spinal muscular atrophy, an autosomal recessive disorder affecting the survival of motor neuron (*SMN*) gene. Genetically affected infants can present at birth or at any time after the newborn period. The severe phenotype presents with paradoxical breathing, tongue fasciculations, areflexia, and generalized weakness more evident in the proximal muscle groups (refer to Chapter 146). Infants with later onset symptoms can have preserved reflexes at the time of presentation with mild increase in creatine kinase level. The diagnosis is confirmed by genetic testing. Other diagnostic tests such as EMG/NCS and muscle biopsy are rarely indicated. On EMG/NCS, fasciculations and reduced compound motor action potential amplitude are observed in affected muscles. Consensus statements for standard of care emphasize interdisciplinary care. Prompt diagnosis and initiation of disease-modifying treatment is necessary to affect the optimal outcome. Spinal muscular atrophy with respiratory distress type 1 (SMARD1) or *infantile axonal neuropathy with respiratory failure* is due to mutation in the *IGHMBP2* gene. A similar phenotype has also been described in a patient with *REEP1* (the gene involved in *SPG3*) mutation but with clinical signs of upper motor neuron involvement. Children with SMARD1 present with respiratory failure and progressive distal weakness. Nerve conduction studies usually show absent responses. Nerve biopsy demonstrates decreased myelinated fibers, active axonal degeneration or active evidence of regeneration, and no onion bulb formations.

Poliomyelitis is an infectious cause of anterior horn cell dysfunction, with asymmetric limb weakness, respiratory insufficiency, and meningeal irritation. The CSF studies show pleocytosis and elevated protein. Treatment is mostly supportive. An effective vaccine has significantly reduced the global incidence. Acute flaccid myelitis is a polio-like illness. The involvement of anterior horn cell and spinal cord gray matter results in asymmetric weakness, areflexia, urinary retention, and respiratory failure. The CSF shows pleocytosis and elevated protein. The Centers for Disease Control and Prevention (CDC) reports a seasonal increase in incidence between August and October, associated with enterovirus infection, especially enterovirus D68. Testing for poliovirus has been negative in affected children. In 2018, the CDC reported 233 cases of acute flaccid myelitis in 41 states, with the average age of affected patients being 5 years. Treatment is supportive and rehabilitation services facilitate long-term outcomes.

Brachial Plexus Palsy

Obstetrical brachial plexus palsy (BPP) is the most common cause in the newborn. However, other causes include familial congenital BPP and structural causes such as uterine malformation or lesions involving the proximal head of the humerus, the cervical vertebrae, or the first rib. Risk factors for obstetrical BPP include shoulder dystocia, large birth weight, vaginal deliveries associated with vacuum extraction, or direct compression of the fetal neck during delivery by forceps, as these maneuvers can cause stretching of the cervical nerve roots (via misdirected traction or hyperextension of the arms).

The BPP are divided into four categories based on location of injury: (1) upper (Erb palsy, C5-C7, most common palsy presenting with adducted arm that is internally rotated at the shoulder; wrist is flexed and fingers are extended in a "waiter's tip" posture), (2) intermediate (C7 and sometimes C8 and T1), (3) lower (Klumpke paralysis—C8, T1—poor hand grasp with more intact proximal muscles), and (4) total plexus palsy (C5-C8 and sometimes T1—second most common and the most devastating—claw hand and flaccid arm with no sensation). An additional finding that may be associated with a poor prognosis is Horner syndrome.

Investigations include x-rays of the chest, spine, and upper limbs to screen for associated lesions (fracture of ribs, transverse process, clavicle, humerus, or phrenic nerve injury). An MRI of the upper limb/shoulder and spinal MRI also is helpful to rule out nerve root evulsion. Computed tomography myelography may be used if MRI is not possible. An EMG/NCS supports documentation of the severity of the neural lesion and detects signs of reinnervation. Serial EMG/NCSs within the first 48 hours after birth will distinguish between prenatal and obstetric causes of BPP. Sensory-evoked potentials can be used to assess the integrity of sensory conduction.

Supportive therapy to maintain passive range of motion and muscle strength is recommended. The majority (70%-95%) of patients with BPP make complete spontaneous recovery, but both the extent (upper, lower, total) and the severity (avulsion, rupture) of the injury influence the prognosis (lower plexopathies tend to be more severe). A small proportion of infants, managed conservatively, have severe permanent disability. The optimal timing of surgical exploration remains controversial, but most recommendations are for intervention in the first 6 months of life if there is no evidence of meaningful clinical recovery such as bicep flexion overcoming gravity.

Peripheral Neuropathy

Peripheral neuropathies in early infancy are rare and can present with hypotonia, weakness, sensory alteration, areflexia,

contractures, ataxia, congenital hip dysplasia, and predominantly distal muscle wasting. These conditions may be described according to neurophysiologic findings (via EMG/NCS) and findings on nerve biopsy. With advances in genetic testing, nerve biopsy is often not indicated. We describe here only the forms that can manifest at birth or in early infancy. Forms with later onset and the rare acquired causes are described in Chapters 91 and 92. Neuropathies that manifest early in life are more often demyelinating than axonal.

Demyelinating Neuropathies

Early-onset demyelinating neuropathies may occur in isolation or with central hypomyelination or other CNS abnormalities (**Table 141.1**). The investigation of early-onset demyelinating neuropathy should include a workup of potential central nervous involvement.

Early-onset demyelinating neuropathies confined to the peripheral system include congenital hypomyelinating neuropathy or Dejerine-Sottas disease. Severe cases of congenital hypomyelinating neuropathy present at birth with profound weakness, hypotonia, arthrogryposis, and respiratory insufficiency. Tongue fasciculations may be present. Dejerine-Sottas disease describes a clinical phenotype characterized by symptom onset in the first 2 years of life, delayed motor development, hypotonia that predominates in the distal muscles, and ataxia. An NCS show significantly slow conduction velocity (median motor nerve conduction velocity of 12 m/s or less) and even conduction blocks in the most severe forms. An EMG can show signs of active denervation.

Several genes are associated, with additional phenotypic features such as *PMP22* point mutations (sensorineural hearing loss, facial weakness, nystagmus, vestibular dysfunction, ptosis, limited extraocular movements, and bladder symptoms), *MPZ* (Adie pupil), *EGR2* (cranial nerve involvement including tongue fasciculations), and *CNTNAP1*. Patients with SH3TC2 or KIAA1985, also referred to as *CMT4C*, may present with early-onset severe spinal deformities, often as the presenting symptom. Foot deformity is common and may precede weakness. Hearing loss is the most common form of cranial nerve involvement, although facial weakness, nystagmus, and tongue atrophy/fasciculations are also reported. Respiratory insufficiency or hypoventilation may also occur.

Axonal Neuropathies

In addition to hypotonia, infants with axonal neuropathy can have pyramidal tract involvement or optic atrophy in *MFN2*; congenital foot deformities (often talipes equinovarus), early contractures, congenital hip dysplasia, scoliosis, vocal cord paresis presenting as stridor or respiratory distress due to diaphragmatic involvement in *TRPV4*; and vocal cord paresis, diaphragmatic dysfunction with restrictive lung disease, and optic atrophy in *GDAP1*. The NCSs show a mixed axonal sensory neuropathy with abnormal velocities. Motor and sensory responses may be unrecordable. Nerve biopsy shows severe loss of large, myelinated fibers and abnormal aggregations of small, round mitochondria on electron microscopy. Autosomal dominant axonal neuropathy can be caused by mutations in several genes like *KIF1B* and *MFN2* (CMT2A), *RAB7* (CMT2B), *TRPV4* (CMT2C), *GARS* (CMT2D), *NEFL* (CMT2E), *HSPB1* (CMT2F), *MPZ* (CMT2I), *GDAP1* (CMT2K), *HSPB8* (CMT2L), and *AARS* (CMT2N). Associated CNS involvement is seen in infantile neuroaxonal dystrophy (*PLA2G6*) or with *Twinkle* mutations with severe encephalopathy, abnormal eye, and limb movements and deafness.

TABLE 141.1 Differential Diagnosis Hypotonic Infant

Central causes:
1. *Vascular*
   A. Hypoxic-ischemic encephalopathy
   B. Intraventricular hemorrhage
   C. Ischemic or hemorrhagic stroke
2. *Structural*
   A. Brain malformations
   B. Cerebral palsy
   C. Intracranial neoplasms
3. *Metabolic*
   A. Toxic metabolites
   B. Energy metabolism
   C. Intracellular small molecules
4. *Systemic*
   A. Congenital infections
   B. Sepsis/CNS infection
   C. Endocrine disorders
   D. Electrolyte disturbance
5. *Chromosomal disorders*
   A. Prader-Willi syndrome
   B. Trisomy 21
   C. DiGeorge syndrome
6. *Spinal cord*
   A. Dysraphism/spina bifida
   B. Ischemic injury

Peripheral causes:
1. *Anterior horn cell*
   A. Spinal muscular atrophy 5q
   B. SMARD1
   C. Poliomyelitis
   D. Acute flaccid myelitis
2. *Brachial plexus injury*
   A. Erb palsy
   B. Klumpke palsy
3. *Peripheral nerve*
   A. Demyelinating neuropathies
      i. Early-onset demyelinating neuropathies with CNS involvement
         a. Waardenburg syndrome and Hirschsprung disease: *SOX10*
         b. Severe forms of Cockayne syndrome: *ERCC6* and *ERCC8*
         c. Krabbe disease: *GALC*
         d. Merosin-deficient congenital muscular dystrophy: *LAMA2*
         e. Navajo neurohepatopathy: *MPV17*
         f. Congenital disorders of glycosylation: multiple genes
         g. Congenital cataracts, facial dysmorphism, and neuropathy: *CTP1*
         h. POLG-related hepatocerebral mtDNA depletion syndromes: *POLG1*
         i. Leigh syndrome: multiple genes
         j. *PRUNE1*
         k. *PTRH2*
   B. Axonal neuropathies
      i. Early-onset axonal neuropathy with CNS involvement
         a. Infantile neuroaxonal dystrophy (INAD): *PLA2G6*
         b. *Twinkle* mutations with severe encephalopathy, abnormal movements, and deafness
   C. Mixed neuropathies
4. *Neuromuscular junction*
   A. Transient neonatal myasthenia gravis
   B. Fetal acetylcholine receptor inactivation syndrome (FARIS)
   C. Congenital myasthenic syndromes
   D. Infantile botulism
5. *Muscle*
   A. Congenital muscular dystrophies
      i. Merosin deficient
      ii. Congenital disorders of glycosylation
      iii. Congenital myotonic dystrophy
   B. Congenital myopathies
      i. Nemaline myopathy
      ii. Central core myopathy
      iii. Myotubular myopathy
   C. Metabolic myopathies
      i. Acid maltase deficiency (Pompe disease)
      ii. Mitochondrial myopathy

Abbreviations: CNS, central nervous system; mtDNA, mitchondrial DNA; POLG, DNA polymerase subunit gamma; SMARD1, spinal muscular atrophy with respiratory distress type 1.

Mixed Axonal and Demyelinating Neuropathy

Severe, early-onset cases can be caused by dominant or recessive mutations in *NEFL*. Pes cavus is frequent. Additional features include intellectual disability, pyramidal signs, hearing loss, ataxia, and tremor. The NCSs show mixed axonal and demyelinating features. Compound motor action potentials are usually moderately to severely reduced, and distal motor latencies may be significantly prolonged. *SPTBN4* mutation has been found in more complex and severe syndromes starting at birth and associated with CNS involvement and including a mainly axonal neuropathy

Neuromuscular Junction Disorders

Infant Botulism

In 2016, the CDC reported 205 confirmed cases of botulism of which 150 (73%) were in infants. The 150 cases of infant botulism were reported from 29 states and the District of Columbia, with California reporting the most (n = 47; 32%). The median age of patients was 4 months (range: 0-10 mo) with no reported deaths.

Infant botulism results from the ingestion of *C botulinum* spores. This bacterium is a gram-positive spore that produces seven different toxins (A → G), and only types A, B, E, and F are known to cause disease in humans. Upon ingestion of *C botulinum* spores, colonization occurs in the infant's intestinal tract, which lacks the competitive microbial flora that normally inhibits growth of ingested spores. The spores then produce neurotoxins that are absorbed into the blood and eventually bind to the presynaptic nerve terminals. This prevents the binding, fusion, and release of acetylcholine and causes a symmetric, descending motor weakness, and flaccid paralysis with autonomic dysfunction.

Botulinum toxicity often presents with acute manifestations of pupillary dilation and paralysis, ophthalmoplegia, feeding difficulties, decreased gag, bulbar palsy, ileus, constipation, hypotonia, weakness, decreased tendon reflexes, and apneic spells. Hypotension, neurogenic bladder, and other signs of autonomic dysfunction can occur early in the course of the disease. Diagnostic triad on EMG/NCS include compound muscle action potentials of decreased amplitude in at least two muscle groups, tetanic and posttetanic facilitation defined by an amplitude of more than 120% of baseline, and prolonged posttetanic facilitation of more than 120 seconds and absence of posttetanic exhaustion. The diagnosis is confirmed by the recovery of the bacterium and the exotoxin in the feces. Stool samples should be collected carefully, as the botulinum toxin is poisonous.

Prompt recognition and diagnosis is imperative for treatment. Supportive care is the mainstay of treatment, with inpatient observation and management of respiratory and feeding complications. Baby botulinum immune globulin is available only to infants who are diagnosed with suspected botulism within 7 days of hospital admission and after consultation with an Infant Botulism Treatment and Prevention Program physician. The use of botulinum immune globulin shortens hospital stay and reduces the need for mechanical ventilation and tube feeding. Infants are expected to make a complete recovery if spared any secondary complications.

Myasthenia

Infants born to myasthenic mothers are at risk for transient neonatal symptoms from passive transfer of maternal acetylcholine receptor antibodies across the placenta. Symptoms include hypotonia and generalized weakness, weak cry, facial palsy, respiratory insufficiency, and feeding difficulties with a weak gag. Other clues to prenatal onset of symptoms include polyhydramnios (poor fetal swallowing) and arthrogryposis (reduced fetal movements). Diagnosis is confirmed by detection of circulating serum acetylcholine receptor antibodies and demonstration of decremental response on repetitive nerve stimulation at 3 to 5 Hz. Supportive care is the mainstay of treatment, with more severe symptoms benefiting from acetylcholinesterase inhibition. Symptoms improve over days to weeks. Rarely, mothers who have antibodies to the fetal subunit of the acetylcholine receptor (γ subunit) have more severely affected infants, either with recurrent miscarriages or infants with transient neonatal myasthenic symptoms that maintain a static facial diplegia and velopharyngeal insufficiency (fetal acetylcholine receptor inactivation syndrome). Prevention for future effected pregnancies include more intensive immunomodulatory treatment of the mother.

Congenital myasthenic syndromes include a number of genetic disorders affecting presynaptic, synaptic, or postsynaptic components of the neuromuscular junction. These conditions are described more completely in Chapter 93. Neonatal or early infancy presentation include hypotonia and muscle weakness, arthrogryposis, facial diplegia, ptosis, ophthalmoplegia, delayed pupillary light reflex, bulbar weakness, weak cry, poor suck, feeding difficulty, episodic decompensation, and episodic apnea. Progressive improvement can be seen in several forms (Dok-7, Rapsyn, CHaT). Treatment is specific to underlying etiology, and options include acetylcholinesterase inhibition, 3,4-diaminopyridine, salbutamol, and fluoxetine.

Muscle Disorders

Myopathies and muscular dystrophies are described more completely in Chapter 147. For metabolic myopathies, refer to Chapters 99, 139, 144, and 147. Congenital myopathies presenting in infancy with hypotonia and weakness include central core disease (*RYR1*), X-linked myotubular myopathy (*MTM1*), and nemaline rod myopathy. Other clinical features include ophthalmoplegia, facial diplegia, respiratory muscle weakness, and bulbar weakness. Congenital muscular dystrophies associated with central abnormalities include those associated with congenital disorders of glycosylation as well as merosin-deficient congenital muscular dystrophy. Infants born to mothers with myotonic dystrophy are typically more severely affected than their mothers due to anticipation in this triplet repeat disorder. Characteristic facial diplegia, tented upper lip, and temporal hollowing is observed, with respiratory distress and feeding difficulties in infants who have over 1,500 repeats (congenital myotonic dystrophy). Screening for cardiac arrhythmia, cataracts, and endocrine disorders is needed, and these children can have significant impairment across developmental domains. Diagnosis is confirmed by genetic testing; clinical myotonia is absent in infancy but observed later in childhood. Myotonia, however, can be readily detected in the mother when the diagnosis is suspected in the newborn infant.

Metabolic myopathies associated with glycogen storage disorders such as acid maltase deficiency (Pompe disease) can have neonatal presentation and should be suspected with cardiomyopathy. Early diagnosis of Pompe disease allows early institution of enzyme replacement therapy, which minimizes morbidity and prolongs survival. Mitochondrial myopathies can also present

with infant hypotonia, such as cytochrome c oxidase deficiency. Investigations to consider are serum creatine kinase, brain imaging, EMG/NCS, isoimmune electrophoresis for transferrin, and genetic testing. A normal creatine kinase level can be observed with several congenital myopathies.

142 Disorders of Motor and Cognitive Development

Jason B. Carmel, Toni S. Pearson, and Reet Sidhu

KEY POINTS

1. Childhood is not only a time of increased brain plasticity but also a time of increased vulnerability.
2. Malformation or injury of the developing brain can result in deficits of several neurologic functions.
3. If there is impaired movement, then the condition is called *cerebral palsy*, which often affects other nervous system functions, including sensation and cognition.
4. If the impairment is cognitive and affects overall intelligence, then the condition is called *intellectual disability*.
5. Autism spectrum disorder is a developmental disorder that primarily affects social and language function.
6. If multiple neurologic functions are affected, the impairment is known as *global developmental delay*.

INTRODUCTION

Infancy and early childhood are marked by rapid brain growth and development. A wide variety of genetic and environmental factors may affect the immature brain during this period and manifest as a delay in the acquisition of milestones in one or more developmental domains: motor (gross and fine), speech/language, social, and cognitive. The delay may be isolated to one domain. When development in more than one domain is significantly delayed in children younger than the age of 5 years, the term *global developmental delay* (GDD) applies.

Developmental delay is a common reason for referral to a child neurologist. The aims of the initial neurologic evaluation of a child with developmental delay are, first, to confirm the nature and severity of the suspected delay and, second, to characterize any specific findings that may provide a clue to the underlying diagnosis. A detailed history is the key starting point. Items of particular importance include the family history (presence of neurologic or developmental disorders in the siblings, parents, grandparents, aunts, or uncles), perinatal history (complications during pregnancy, birth, or the neonatal period, including prematurity), and history of any coexisting medical problems. With regard to the presenting problem (eg, motor delay), important items include the age at which the initial concern arose, the child's developmental progress over time, and whether or not there has been developmental regression. On general examination, the child's head circumference, height and weight, and the presence of any dysmorphic features should be noted. The eyes and optic fundi should be thoroughly examined, and skin should be checked for stigmata of neurocutaneous syndromes. Specific features of interest in the neurologic examination will be outlined in the relevant sections in the following text.

DISORDERS OF MOTOR DEVELOPMENT

The acquisition of motor skills features prominently in the first year of life (Table 142.1). As a result, conditions that affect the motor system often present during infancy with motor developmental delay. Motor delay may also be the first manifestation of a condition that affects development globally because impaired motor function becomes apparent earlier than impairments in other domains, such as cognition and language. Motor delay may be accompanied by specific motor symptoms such as increased appendicular tone ("stiff"), decreased axial tone ("floppy"), and involuntary movements.

TABLE 142.1 Motor Developmental Milestones in the First 5 Years[a]

Gross Motor	Age Range
Hold head steady	2-4 mo
Roll over	2-5 mo
Sit without support	5½-7 mo
Pull to stand	8-10 mo
Walk	11-15 mo
Run	14-20 mo
Jump	21-28 mo
Hop	3-4 y
Balance on one foot for 4 s	3½-5 y
Fine Motor	**Age Range**
Grasp rattle	3-4 mo
Reach	4-6 mo
Transfer objects	5-8 mo
Pincer grasp	7-10 mo
Scribble	12-17 mo
Feed self with spoon	13-18 mo
Stack two blocks	13-21 mo
Hold crayon using fingers (not fist)	2-3 y
Copy a circle	3-4 y
Refined tripod pencil grip, print own name, copy a square	4-5 y

[a]Age range indicates approximately the 25th to 90th percentile for each milestone according to the Denver II Developmental Screening Tool.

Approach to the Child With Motor Delay

The neurologic examination begins with observation, particularly in the infant or toddler. Observe the child's spontaneous posture and movements for asymmetry, paucity of movement that may hint at weakness, abnormal postures, and excessive or involuntary movements. On cranial nerve examination, look for eye movement abnormalities including restricted range of movement and nystagmus. If the child can speak, note whether speech is clear or dysarthric. Turning attention to the body, assess muscle tone in the trunk and limbs. Low truncal tone is common to many disorders that present with motor delay in infancy. Are the limbs hypotonic or spastic (a rate-dependent increase in tone)? Check whether tendon reflexes are abnormally brisk, suggesting an upper motor neuron lesion, or reduced, suggesting an abnormality of the lower motor neuron, nerve, or muscle. Assess coordination on targeted reaching movements (looking for dysmetria) and, in an older child, rapid alternating movements such as repetitive hand tapping. If the child is able, ask them to rise to standing from the floor (looking for a Gowers sign, which indicates proximal leg weakness). Note whether the gait is narrow or wide-based and steady or unsteady. If involuntary movements are present, note their body distribution, their quality (eg, sustained, writhing, or jerky), whether they are random or repetitive and stereotyped, and in what contexts they appear (eg, at rest, during movement).

Following the clinical evaluation, neuroimaging may be considered and directed by the history and examination. Magnetic resonance imaging of the brain is indicated if there is a history of developmental regression, marked micro- or macrocephaly (>2 standard deviations from the mean), abnormal rate of head growth, or any abnormalities on neurologic examination including cranial nerve dysfunction, focal weakness, spasticity, abnormally brisk reflexes, or involuntary movements. Other investigations, such as genetic testing, may be indicated by the clinical syndrome or brain imaging results. In all cases, the aim is to determine a specific etiologic diagnosis whenever possible in order to guide the most appropriate management strategy. If the clinical syndrome and brain imaging findings are compatible with a developmental malformation or acquired brain lesion, then symptomatic management will be the most important consideration (see "Cerebral Palsy" section in the following text). On the other hand, several individually rare genetic and metabolic disorders may present with motor delay and mimic cerebral palsy (CP). It is vital that the child neurologist be alert to signs that may indicate one of these conditions (Table 142.2).

TABLE 142.2 Features That Should Prompt Evaluation for a Possible Genetic or Metabolic Disorder in a Child Presenting With Symptoms of Cerebral Palsy

- Parent or sibling with a neurologic disorder
- Absent history of perinatal complications
- Normal brain imaging
- Developmental regression
- Progressive neurologic symptoms
- Ataxia or involuntary movements
- Signs of peripheral neuromuscular disease (reduced or absent reflexes, sensory loss)
- Fluctuating motor symptoms, for example, diurnal variation, worsening during fasting or exercise (may be symptoms of a treatable condition, eg, a neurotransmitter disorder or GLUT1 deficiency syndrome)

Abbreviation: GLUT1, glucose transporter 1.

Making the correct diagnosis in these cases has important implications for management. In some cases, there is a disease-specific treatment that may dramatically improve the clinical course. Even if no disease-specific treatment yet exists, accurate diagnosis makes it possible to provide prognostic information and genetic counseling regarding recurrence risk in future pregnancies to the family.

Cerebral Palsy

CP is defined as an insult to the developing brain that impairs movement or posture. CP is an umbrella term that describes a group of disorders (the cerebral palsies) characterized by motor impairment due to a developmental anomaly or nonprogressive brain lesion that arose in the developing fetal or infant brain. The term *cerebral palsy* remains useful if considered not as a diagnosis in itself, but rather as a descriptive term that has widespread familiarity and conveys a recognized set of clinical characteristics and medical needs.

CP is common, with a birth prevalence of 2 or 3 per 1,000 live births in developed countries. Risk factors include a history of prematurity, intrauterine growth retardation, multiple gestation, intrauterine infection, and antepartum hemorrhage. One common misconception is that CP is usually caused by birth asphyxia. Although ascribing etiology has challenges, the rate of perinatal asphyxia is likely less than 20%. Other causes of CP include periventricular leukomalacia (the most common form of brain injury in very preterm infants), cerebral malformations, stroke, and infection. The etiology is usually, but not always, evident on brain imaging.

CP may be classified according to the predominant motor abnormality: spasticity, dyskinesia (involuntary movements including dystonia, chorea, or athetosis), or ataxia. In most cases, there is a mixture of more than one motor feature, such as spasticity and dystonia. CP may be further classified according to the body regions that are primarily affected: diplegia (both legs), quadriplegia (all four limbs), and hemiplegia (one side of the body). An accurate characterization of the motor syndrome is important for two reasons. First, it assists the interpretation of the clinical history and brain imaging findings in establishing the etiology of a child's CP. Second, it guides management decisions.

Spastic Diplegia

Approximately, one-third of children with CP have spastic diplegia (or diparesis), in which spasticity is predominantly found in the legs. The arms may be mildly affected or unaffected. Parents may notice leg stiffness and a tendency for the legs to cross ("scissoring") due to increased tone in the hip adductor muscles. The increased lower limb tone may lead an infant to roll over or bear weight through the legs at an atypically early age. An older child with mild to moderate symptoms may have a narrow-based, scissoring gait and toe walking. On examination, there is increased tone in the legs, particularly hip adductors, hamstrings, and calves. Tendon reflexes are brisk, and plantar responses are extensor. The most commonly associated brain imaging abnormality is bilateral periventricular white matter lesions, particularly in children with a history of prematurity. The white matter lesions may be periventricular leukomalacia, consequences of intraventricular hemorrhage, or both.

Spastic Quadriplegia

Spastic quadriplegia (found in 20%-25% of children with CP) is often the most severe form. Quadriplegia is frequently associated with diffuse brain injury or dysgenesis, but one side may be more

affected than the other. Brain imaging may demonstrate abnormalities in both gray and white matter. The most common alteration in tone is axial hypotonia (weak neck and trunk) and limb hypertonia (spasticity). A subset of patients has lesions in the deep gray nuclei (basal ganglia or thalamus) and may have a coexisting movement disorder. Most children with spastic quadriplegia are unable to walk and are dependent on a wheelchair for mobility and on support from caregivers for daily activities. Due to the diffuse nature of the brain injury, a number of comorbidities are often present, including seizures, cognitive impairment, sensory impairments, and speech/swallowing difficulties. If swallowing is impaired, a feeding gastrostomy may be required to ensure adequate nutrition. For children who have both the inability to speak and limited voluntary control of hand movements, communication can be very challenging. Effective use of a communication device such as a board or tablet to which the child can point, or devices with eye tracking capability, may vastly improve the quality of life for both the child and his/her caregivers.

Spastic Hemiparesis

Spastic hemiparesis is found in about one-third of children with CP and results from a unilateral brain lesion, such as a cerebral infarct (often in the territory of the middle cerebral artery), focal malformation (eg, schizencephaly, cortical dysplasia), or periventricular hemorrhagic infarction. Such lesions may have been acquired prenatally or perinatally, but symptoms tend to manifest around age 6 months, when parents notice that the child exhibits a strong preference to use one hand over the other. Handedness normally develops at age 2 to 3 years, and so an obvious hand preference younger than 12 months of age should prompt clinical evaluation for a hemiparesis.

The hemiparesis usually affects the arm and hand more than the leg. Children with spastic hemiplegic CP are able to walk, although walking may be delayed, and an asymmetric gait pattern with toe walking and circumduction of the affected leg is observed. In mild cases, upper limb weakness may only be evident as a subtle loss of hand dexterity or abnormal arm posturing during running. On the other hand, large lesions that involve both the white matter and the cortex can be associated with pronounced weakness as well as cortical sensory loss, leading to little or no functional hand use. Speech and language development is often delayed in the setting of a unilateral lesion of either hemisphere, but most children develop age-appropriate spoken language by the time they enter school. Longitudinal follow-up studies describe the emergence of subtle cognitive weaknesses in school-aged children with a history of perinatal stroke. Seizures are an additional factor that may adversely impact long-term cognitive outcome.

Dyskinetic Cerebral Palsy

Involuntary movements are the predominant motor finding in 5% to 10% of children with CP. The majority of children with dyskinetic CP have a history of term birth. Several types of involuntary movements may occur either alone or in combination. *Dystonia* describes stereotyped, abnormal twisting postures that may be fixed or intermittent. When severe dystonia causes fixed postures that make the limb appear hypertonic, it may be difficult to distinguish from severe spasticity. *Athetosis* refers to continuous writhing or wriggly movements, whereas *chorea* appears as discrete, random-appearing, jerky movements. Children with dyskinetic CP often have low tone that develops during infancy. A key feature of the involuntary movements is their tendency to worsen with increased activity or attempts to initiate voluntary movement. Often, muscles of the face and neck are involved in addition to the trunk and limbs.

Basal ganglia lesions are the most common abnormality seen on brain imaging in children with dyskinetic CP. These lesions may result from hypoxic-ischemic injury (in which cortical injury is also often seen) or neonatal hyperbilirubinemia (*kernicterus*, usually caused by maternal-fetal blood group incompatibility and now rare in developed countries). In instances where the cortex is spared, children may have good cognitive function despite severe motor disability and speech impairment.

Ataxic Cerebral Palsy

Ataxic CP is the least common form of CP (<5%) and is characterized by hypotonia, trunk and gait ataxia, and limb ataxia (intention tremor, dysmetria). If speech is affected, dysarthria with a slow and scanning quality is typical. Brain imaging may demonstrate a cerebellar malformation or lesion, although it is often normal. Both dyskinetic and ataxic CP are associated with normal brain imaging in a significant proportion of children (approximately one-third and one-half, respectively). In these cases, it is important to consider further investigation for an underlying treatable or neurodegenerative condition (**Table 142.3**).

TABLE 142.3 Selected Genetic Conditions That May Mimic Dyskinetic and Ataxic Cerebral Palsy

Condition	Features
Neurotransmitter disorders	Hypotonia, dystonia with diurnal variation (better in morning and after sleep), oculogyric crises. Diagnosed by CSF neurotransmitter metabolite assay, genetic testing. Many forms respond to levodopa treatment.
GLUT1 deficiency syndrome	Seizures, acquired microcephaly, ataxia, spasticity, dystonia, paroxysmal dyskinesia (may be triggered by exercise, fasting); treatment: ketogenic diet
Creatine deficiency	Intellectual disability, seizures, autism, progressive dystonia in GAMT deficiency; treated with creatine monohydrate supplementation.
Benign hereditary chorea	Hypotonia, chorea, dystonia, myoclonus; may be associated with hypothyroidism, neonatal respiratory distress, or asthma
Lesch-Nyhan syndrome	Hypotonia, dystonia, self-injurious behavior, elevated plasma urate
Ataxia-telangiectasia	Slowly progressive ataxia; chorea; dystonia (involuntary movements may precede onset of ataxia); oculocutaneous telangiectasia; immunodeficiency; elevated serum α-fetoprotein; reduced levels of serum IgA, IgE, IgG_2
Pelizaeus-Merzbacher disease	Initial hypotonia then spastic quadriparesis, ataxia, ± dystonia and chorea, nystagmus (in classic form)
Niemann-Pick disease type C	Initial hypotonia followed by vertical supranuclear gaze palsy, slowly progressive ataxia, dystonia; ± hepatosplenomegaly

Abbreviations: CSF, cerebrospinal fluid; GAMT, guanidinoacetate methyltransferase; GLUT1, glucose transporter 1; Ig, immunoglobulin.

Management of Cerebral Palsy

Children with CP should be referred to a multidisciplinary specialty center and to an early intervention program for therapy services as soon as they are identified. Hearing and vision should both be assessed early. Interventions are directed toward (1) spasticity management; (2) management of involuntary movements; and (3) improvement of strength, motor abilities, function, and self-care. Effective management requires regular follow-up as the child grows and develops so that realistic expectations and achievable goals can be set and periodically reevaluated.

Spasticity management aims to reduce hypertonia in order to maximize the child's ability to gain muscle strength and range of movement through physical therapy and to prevent long-term complications such as joint contractures and deformity. Functional goals depend on the severity of the child's impairment. For example, the goal for a child with moderate spastic diparesis may be to achieve independent ambulation. In a child with severe spastic quadriplegia, seizures, and intellectual disability (ID), the goal may be to improve patient comfort and ease care during daily activities such as dressing and bathing. The effect of spasticity on a child's posture and motor function can change over time, often increasing noticeably during periods of rapid growth. Thus, although CP is caused by a nonprogressive brain lesion, the signs and symptoms change with time.

Botulinum toxin injections are an effective tool for reducing spasticity, particularly when targeted toward a limited number of muscle groups. The toxin's effect lasts approximately 3 to 4 months, so injections typically need to be repeated up to 3 times per year. Short-term efficacy must be weighed against emerging evidence for injections causing muscle fibrosis. Sometimes, injections may be combined with serial casting to treat mild contractures. Oral medications such as baclofen (starting dose: 2.5-5 mg/d) and diazepam (starting dose: 1-5 mg/d depending on age and size) are useful when symptoms are generalized and offer modest benefit, but side effects such as sedation often limit the dose and efficacy.

Neurosurgical options for the management of spasticity include placement of an intrathecal baclofen pump and selective dorsal rhizotomy. Compared to oral baclofen, intrathecal baclofen may achieve a greater reduction in spasticity and dystonia, particularly in the legs, with fewer side effects. However, this potential benefit must be weighed against the long-term effort needed to maintain the pump and risk of complications. Rhizotomy aims to produce a permanent reduction in tone and is a good treatment option for some patients. Traditionally, the "ideal" rhizotomy candidate has been an ambulating child aged 3 to 8 years with spastic diparesis, in whom the goal of surgery is to optimize gait and independent function. Rhizotomy may also be appropriate in selected patients with spastic quadriparesis in order to ease caregivers' burden of care and reduce the need for future botulinum toxin injections and orthopedic procedures. If musculoskeletal complications such as joint contractures develop despite medical and surgical attempts to control spasticity, orthopedic surgery (such as tendon release procedures) may be indicated. Orthopedic realignment may be important for achieving functional goals.

Children with dyskinetic CP often benefit from symptomatic treatment of their involuntary movements. For dystonia, trihexyphenidyl, starting at a low dose (1-2 mg/d) and titrated gradually to the point of tolerance (with common side effects being sedation, constipation, and urinary retention), may reduce abnormal posturing. Levodopa (starting dose: 25-50 mg/d) is beneficial in some children with dystonic CP. Hyperkinetic movements, such as chorea or athetosis, may respond to tetrabenazine (starting dose: 6.25-12.5 mg/d). Deep brain stimulation, with electrodes placed in the globus pallidus pars interna, may be a surgical option in severe, treatment-refractory cases of dyskinetic CP, although experience regarding efficacy and long-term outcome remains limited.

The rehabilitation team, composed of a physiatrist; orthotist; and physical, occupational, and speech/language therapists, plays an essential role in the care of a child with CP. Physical therapy aims to improve strength and quality of movement, train function, and maintain range of motion. Occupational therapy focuses on arm and hand movement control and building independence in daily activities. Speech and language therapy focuses on communication. It is important to assess the child's home and school environments and determine equipment to facilitate mobility, independence, and functional communication.

Although diagnosed during childhood, CP is a lifelong condition, and there are more adults living with CP than children. Interventions made early in life must consider the long-term consequences of the intervention. Children with severe motor and ID will require lifelong care, either from a parent or relative or in a nursing home setting. Less affected children need a school and therapy program targeted to their abilities, aiming to maximize their potential for future independence and well-being.

Developmental Coordination Disorder

Developmental coordination disorder (DCD) affects about 5% to 6% of children and is characterized by subtle impairments in gross and fine motor skills that typically manifest as difficulties in daily activities such as dressing, writing, or learning to ride a bike. Affected children are often described as "clumsy." In contrast to CP, the neurologic examination in DCD is normal apart from subtle signs such as mild hypotonia and dysdiadochokinesia. The underlying neurophysiologic basis remains poorly understood. DCD often co-occurs with other developmental disorders including attention deficit hyperactivity disorder (ADHD), learning disabilities, and speech/language impairment.

DISORDERS OF HIGHER CEREBRAL FUNCTIONS

Assessment of speech and language, cognitive, academic, and reciprocal social abilities is an essential component of the evaluation of a child with developmental delay. The disorders that affect these domains of development are all defined behaviorally, lacking a single biologic marker or gold standard diagnostic instrument. Consequently, thorough assessment is crucial for proper diagnosis and effective management. The groups of developmental disorders of higher cerebral development under consideration are listed in Table 142.4.

Approach to the Child With Language, Cognitive, or Academic Delays

The age and manner in which children acquire speech and language varies considerably. Knowledge of normal developmental language milestones is essential in order to properly assess

TABLE 142.4 Developmental Disorders of Higher Cerebral Functions

Disorder	Function Affected	Location of Brain Dysfunction
Intellectual disability	Cognition	Diffuse or multifocal
Dysphasia (developmental language disorder)	Oral language	Language systems
Dyslexia (reading disability)	Written language (phonologic processing)	Language systems (left perisylvian)
Dyscalculia (math disability)	Math (spatial cognition)	Posterior right hemisphere
Nonverbal learning disability (NVLD)	Visuospatial, math, social cognition	Right parietal
Attention deficit hyperactivity disorder (ADHD)	Focused attention (executive functioning)	Prefrontal
Autism spectrum disorders (ASDs)	Social cognition	Connectivity

a child (Table 142.5). Speech and/or language delays are one of the most common presenting complaints to a child neurologist, especially in toddlers and preschool children. Hearing impairment must be excluded in all children with speech and language delays. The main diagnostic considerations in toddlers/preschoolers are developmental language disorders, autism spectrum disorders (ASDs), ID, and ADHD, although a definitive diagnosis of the latter may be postponed until a child is older if symptoms are not severe.

The mental status examination is the most informative part of the neurologic examination in the evaluation of a developmental disability involving cognitive function. The mental status exam in the toddler/preschooler relies heavily on observation. Watch the child play with representational toys (eg, tiny dolls in a dollhouse, cars and trucks at a fire station, people and animals at a farm), assess his or her ability to talk to and play with the examiner or parent, and observe his or her interest and ability to focus on an activity introduced by another person (playing ball,

TABLE 142.5 Language and Social/Emotional Milestones

Age	Receptive Skills	Expressive Skills	Social/Emotional
0-2 mo	Startle, eye widening to sound	Range of cries (from hunger to pain)	Smiles spontaneously
2-4 mo	Quiets to voice, eye blinking to sound	Coos in response to voice	Smiles responsively
4-9 mo	Head turns to sound, responds with raised arms when mom says "up" and reaches for child, responds appropriately to friendly or angry voices	Babbling, repeats self-initiated sounds	Laughs to social attentions
9-12 mo	Listens selectively to familiar words, begins to respond to "no" and to one-step commands (usually accompanied by gesture), understands 10 words	Repeats parent-initiated sounds, symbolic gestures, jargoning, says "mama/dada" nonspecifically	Responds and plays social games: pat-a-cake, peek-a-boo. Joint attention emerges.
12-18 mo	Points to three body parts, understands up to 50 words, recognizes common objects by name, follows one-step commands accompanied by gestures	Uses words to express needs, 10 words by 18 mo, word usage may be inconsistent and mixed with jargon	Responds to name, joint attention established, functional play
18 mo-2 y	Points to pictures when asked "show me," begins to distinguish "you" from "me"	Telegraphic two-word phrases "go bye-bye," "mama up," "baby go"; 2 y: vocabulary of at least 50 words and 50% intelligible by strangers	Symbolic play (feed baby, mix food in bowls)
2 ½ y	Follows two-step commands, can identify actions in pictures and objects by use	Two- to three-word sentences develop, adjectives and adverbs appear, begins to ask questions	Imaginative play
3 y	Knows several colors; knows what to do when we are hungry, thirsty, or sleepy; aware of past and future, understands "today" and "not today"	Uses pronouns and plurals, sentence length increases to three to five words, can tell stories that begin to be understood; uses negatives "I can't" and "I won't"; verbalizes toileting needs; tells full name, age, and gender	Starts to join in play with other children, begins dramatic play
3 ½ y	Answers questions as "do you have a doll?" and "what toys do you have?"	Can relate experiences in sequential order, asks for permission	More independent in play with other children, shares toys and takes turns with assistance
4 y	Understands same versus different, can follow three-step commands, understands why we have houses, umbrellas . . .	Can tell a story, uses past tense, names primary colors, asks many questions, nearly all speech understood by strangers	Fully plays and interacts with other children, improving in turn taking and cooperation, very imaginative with self and others
5 y	Understands what we do with eyes and ears; understands "if," "because," "when," "why"; understands differences and comparisons; begins to understand left and right	Asks definition of specific words, makes serious inquiries ("how does this work?" "what does it mean?"), language is now complete in structure and form, all parts of speech are used as well as all types of sentences and clauses	Respects reasonable authority, wants to do what is expected, plays games with rules

looking at pictures, drawing). Particular attention should be paid to the child's ability to engage in creative/imaginative play, imitation, behavioral flexibility (ability to switch activities), attention span, and joint attention (the ability to draw another person's attention to an object of interest through the use of eye gaze and gestures, such as pointing).

Speech and/or language disorders can be subdivided based on the area of deficit: expressive or receptive. Expressive disorders can exist in isolation, but receptive disorders always coexist with expressive deficits. Speech and language skills should be assessed in the following areas: (1) production: amount of speech and its intelligibility, fluency, length and syntactic complexity of sentences, and richness of vocabulary; (2) pragmatics: knowing how to engage another person in conversation, turn taking, topic maintenance, appropriate eye gaze, awareness of tone of voice, facial expression, gestures, and body postures; (3) comprehension: following commands, answering simple questions (eg, what's that? where is _?), answering complex, open-ended questions (eg, why? when? how?); and (4) abnormal features: immediate echolalia, delayed echolalia (overlearned scripts), perseveration, abnormal prosody, and narrow range of topics.

In school-age children, school failure or underachievement is a common presenting complaint. In this age group, the differential diagnosis includes those disorders under consideration in the toddler/preschool years but expands to include disorders affecting academic achievement, for example, learning disabilities. Thus, the evaluation of the older child must include an assessment of academics in the areas of reading, writing, spelling, and mathematics. An assessment of cognitive ability is the first step, as the diagnosis of learning disability implies at least average intelligence. Attention should also be evaluated, as ADHD can now be diagnosed more reliably than in the toddler/preschooler. Language screening in the office is best done through a combination of informal assessment (as described for the preschooler) and standardized measures to assess vocabulary, word retrieval, word fluency, and automaticity of retrieval. General fund of knowledge, reading, spelling, writing, arithmetic, drawing (visuospatial skills), attention, and social reciprocity should also be evaluated. These skills can be assessed qualitatively; however, standardized screening tests are advisable to increase reliability.

Many children will come to the office with a detailed quantitative report generated by a psychologist or neuropsychologist detailing the strengths and weaknesses in cognitive, linguistic, and academic domains. It is important to be knowledgeable in the interpretation of these tests and their scores as parents rely on neurologists to synthesize the findings for diagnostic clarification and developing an effective management plan. If a child has not had a formal assessment, it is advisable to have a comprehensive evaluation by a psychologist (preferably a neuropsychologist) and speech language pathologist to assess the child's cognitive and linguistic strengths and weaknesses. This should include a report of school achievement tests when learning disabilities are suspected. Attention disorders (with or without hyperactivity) frequently co-occur with learning disability; therefore, it is essential to diagnose these conditions accurately, as management strategies are quite different (ie, educational vs pharmacologic).

Developmental Language Disorders

Developmental language disorders (DLD), often lumped under the umbrella term *specific language impairment* or *developmental dysphasias*, are a heterogeneous group of disorders characterized by inadequate language acquisition at the expected age despite otherwise normal development. The diagnostic criteria remain controversial, but DLD is usually ascribed when there is evidence that expressive and/or receptive language deficit is not attributable to inadequate hearing, ID, extreme and prolonged social deprivation (not simply social impoverishment), or a known brain lesion. Dysphasias can affect phonology (speech sounds) and syntax (word order, grammar) or higher order language processing skills, for example, semantic (word meaning) and pragmatics (communicative and conversational use of language). Genetics is the major cause of the developmental dysphasias, which occur more frequently in boys than girls.

Autism spectrum disorder is an important diagnostic consideration in any child with a speech and/or language delays. Children with ASDs differ from children with DLD in their lack of drive to communicate. Unlike ASD, children with DLD use gestures, such as pointing and head nodding, which are usually well coordinated with eye gaze and facial expressions. Children with ASD have abnormal features such as echolalia, overlearned scripts, and perseverative language, in addition to the hallmark of impaired social reciprocity (see Chapter 143).

The occurrence of language regression in a child raises alarm in most families and sets off a cascade of neurodiagnostic testing that usually involves performing electroencephalography (EEG). The exceptionally rare acquired epileptic aphasia or *Landau-Kleffner syndrome* (LKS) refers to previously normal children who lose their language skills, usually due to word deafness (ie, auditory verbal agnosia), in the setting of clinical seizures or an epileptiform EEG that is activated in sleep. Electrical status epilepticus during slow-wave sleep (ESES) is the EEG pattern seen in LKS. Similarly, approximately one-third of children with ASDs experience regression during the first 1 to 3 years of life, commonly referred to as *autistic regression*. The EEGs in these children can be epileptiform. Children with autistic regression, however, undergo a more global loss of skills involving language, nonverbal communication, and sociability, unlike those with LKS who tend to maintain nonverbal communication skills and reciprocal social capabilities. The degree of overlap between LKS, ESES, and autistic regression with epileptiform EEG is currently poorly understood, although it is known that ESES is rarely seen in children with a more global autistic regression.

Intellectual Disability

Intellectual disability, also known as *intellectual developmental disorder*, requires limitations in both intellectual ability and deficits in adaptive skills relative to the child's age, experience, and environment. The onset of both deficits must occur during childhood. Deficits in intellectual functioning must be confirmed through clinical evaluation and standardized IQ testing. The IQ definition of ID uses 100 as the mean and 15 as the standard deviation. An IQ score of 65 to 75 (2 standard deviations below the mean, with a variation of +/− 5 points) is the demarcation point. The level and severity of ID (mild, moderate, severe, and profound) is defined on the basis of adaptive skills rather than the IQ score. The definition links the severity of ID to the degree of community support required to achieve optimal independence. Mild ID indicates the need for intermittent support, moderate ID for limited support, severe ID for extensive support, and profound ID for pervasive support. Although both intellectual and adaptive functioning are pertinent in defining ID,

impairment of adaptive function is more likely to be the presenting feature than low IQ; however, it is expected that there is an association between intellectual functioning and adaptive skills.

The term *global developmental delay* is used to describe children younger than the age of 5 years with significant delays in developmental milestones in several areas of functioning. GDD can be diagnosed using a standardized test, which shows performance at least 2 standard deviations below the mean in at least two developmental domains: motor, speech and language, cognition, personal-social, and/or adaptive (daily living). The diagnosis of ID is not used for children younger than age 5 years old because IQ scores are not reliable until after 5 years and because some children with GDD will not meet criteria for ID as they get older.

The prevalence of ID varies due to differences in diagnostic approach, population characteristics, and study design but is generally considered to be 1%. Mild ID represents the majority (85%) and severe ID the minority (0.5%-1%). Those with severe ID are more likely to have a definable etiology, whereas those with mild ID tend to come from socially disadvantaged backgrounds, often with a family history of mild ID or borderline intellectual function. The prevalence of GDD (in children younger than 5 y) is estimated at 1% to 3%.

The yield of diagnostic testing in determining a cause for GDD/ID is quite variable. The diagnostic evaluation should focus on clues for a genetic versus acquired etiology for ID. Recent years have seen important progress in identifying the genes involved in ID and currently, genetic defects are found in approximately 25% to 50%. A history of consanguinity, pregnancy losses/stillbirths, postnatal deaths of prior offspring, or birth defects should raise suspicion for a genetic etiology. If there is a family member known to have GDD/ID, testing specific to the known disorder should be performed, and if not known, a comprehensive genetics evaluation should be initiated. Observed dysmorphic features may prompt specific testing (eg, Down syndrome, fragile X syndrome).

Other neurodiagnostic investigations should be undertaken based on the clinical picture. Inherited metabolic diseases are responsible for 1% to 5% of unspecified ID, and testing should be undertaken if clinical indicators are present. An EEG is appropriate if an underlying epilepsy syndrome is suspected or when there are paroxysmal behaviors concerning for seizures. Neuroimaging is recommended as part of the diagnostic evaluation of a child with GDD. Magnetic resonance imaging is more sensitive than computed tomography (CT), with abnormalities found in approximately one-half to one-third of children with global delay. The chance of detecting an abnormality increases if movement abnormalities, particularly CP, are present.

The management of children with ID focuses on finding the appropriate educational setting for children with mild ID, vocational training for those with moderate ID, and determining home or institutional placement for those with severe and profound ID. Available evidence demonstrates the benefits of early intervention through a variety of programs, at least with respect to short-term outcomes, and suggests that early diagnosis of a child with global delay may improve long-term outcome.

Learning Disabilities

Learning disabilities occur in approximately 10% to 15% of school-aged children and can affect one or more academic skills. Learning disabilities involve reading (dyslexia), spelling (dysorthographia), writing (dysgraphia), mathematics (dyscalculia), and visuospatial skills (nonverbal learning disability [NVLD]). Executive functioning deficits are seen in learning disabilities and also in disorders of attention, for example, ADHD. Specific learning disabilities do not refer to those children whose learning problems result from visual, hearing, or motor handicaps or are a consequence of emotional disturbance, environmental, cultural, or economic disadvantage. The term *learning disability* implies at least average intelligence.

Dyslexia

Developmental dyslexia is the most widely recognized and most common learning disabilities. It occurs in as many as 10% of school-aged children and comprises 80% of learning disabilities. Boys are more often affected than girls. Dyslexia is characterized by an unexpected difficulty learning to read despite at least average intelligence, adequate instruction, and sociocultural opportunity. Major sensory functions must be normal. Dyslexia has a significant genetic component with heritability estimated at 54% to 84%. Dyslexia susceptibility 1 candidate 1 was the first gene reported to be associated with dyslexia. Numerous candidate dyslexia susceptibility genes have subsequently been identified including several that affect neuronal migration.

There are different subtypes of dyslexia but the most common involves impaired phonologic processing. Children with dyslexia have difficulties with accurate and/or fluent word recognition, poor spelling, and decoding abilities. They have problems segmenting and sequencing speech into phonemes (ie, speech sounds). Measures that assess phonologic functioning (eg, segmenting words [say *cowboy* without the *boy*, say *smack* without the *m*], word and nonword blending, sound matching of first and last syllables) best differentiate dyslexic from normal readers.

A history of language delay and/or a family history of reading disabilities are often found in those with dyslexia. The elemental neurologic examination is normal. Routine imaging is normal and unnecessary, except perhaps in children with abnormalities on neurologic examination, seizures, or large discrepancies between verbal and spatial skills. All children with dyslexia should have a formal neuropsychological evaluation to determine their cognitive abilities (strengths and weaknesses) and to determine if there are co-occurring conditions that might affect treatment (eg, ADHD).

Dyslexia is a lifelong disorder; however, most children with early reading problems learn to read at grade level if they are diagnosed by age 8 to 9 years (third or fourth grade) and evidence-based reading instruction is provided. Early diagnosis is essential, as children diagnosed late are likely to continue to have reading problems, even if remediated. Large population studies suggest that some degree of reading disability persists into adulthood in most, and occupational attainment may be lower in some.

Nonverbal Learning Disabilities

Mycklebust and Johnson coined the term *nonverbal learning disabilities* in 1967. It described a predominantly social emotional disorder that in many ways resembled the current concepts of the ASDs but included some spatial difficulties as well. The distinction between NVLDs and high-functioning ASD is widely debated. Some differentiate NVLD from ASD based on the lack of restrictive behaviors and the presence of greater verbal than performance IQ in NVLD. Subtypes of NVLD were subsequently described that involved varying degrees of social cognitive

impairments, visuoperceptual skills, math difficulties, attention, and executive functioning relative to average or above-average reading (decoding) and spelling. NVLD does not appear in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (*DSM-5*), but is referred to by various other names, including *right hemisphere syndrome* and *visuospatial learning disability*. The exact prevalence is unknown largely due to varying definitions but it is generally thought to account for approximately 10% of all learning disabilities.

The basis for the identification of children with NVLDs is usually their higher verbal as compared with performance IQ scores on neuropsychological assessment batteries. This is an indicator of their visuospatial and visuomotor difficulties, which are a core feature of the disorder. A complete neuropsychological evaluation is required for diagnosis. Suggested management for NVLDs often trades on developing verbal strengths to compensate for the nonverbal deficits.

Dyscalculia

Developmental dyscalculia involves any or all aspects of mathematics from difficulties representing and manipulating numeric information to learning and remembering arithmetic facts to executing arithmetic procedures. The prevalence of dyscalculia is approximately 3% to 6%, affecting both genders equally. A developmental Gerstmann syndrome (right/left disorientation, finger agnosia, dysgraphia, dyscalculia, and sometimes constructional apraxia) occurs in as many as 2% of school-aged children. ADHD co-occurs in one-fourth of individuals, and approximately one-fifth have dyslexia.

Comprehensive neuropsychological evaluations are recommended in individuals suspected of having dyscalculia. Children with neuropsychological signs of both left and right hemisphere dysfunction can have dyscalculia. Both groups have similar problems on arithmetic batteries, but those with left hemisphere dysfunction seem to perform significantly worse in addition, subtraction, complex multiplication, and division and also make more visuospatial errors. Math remediation is appropriate for the child with isolated difficulties or with mathematics difficulties in combination with other learning difficulties.

Attention Deficit Hyperactivity Disorder

ADHD begins in childhood with symptoms of hyperactivity, impulsivity, and/or inattention. For children younger than 17 years of age, the *DSM-5* diagnosis requires six or more symptoms of hyperactivity and impulsivity and six or more symptoms of inattention. For individuals 17 years and older, five or more symptoms per category are required. Depending on the predominance of symptoms, ADHD is divided into three subtypes: predominantly inattentive, predominantly hyperactive-impulsive, and combined type. Symptoms of hyperactivity/impulsivity and inattention must occur often; be present in more than one setting, such as school or work and home; persist for at least 6 months; be present before age 12 years; impair academic, social, or occupational functioning; and be excessive for the developmental level of the child.

The reported prevalence of ADHD in school-aged children ranges from 1% to 20%. The *DSM-5* conservatively estimates the prevalence of ADHD as about 5% of children and 2.5% of adults in most cultures. The variation in prevalence is secondary to differing techniques of ascertainment and invariably reflects the lack of a biologic marker for the disorder. ADHD occurs approximately twice as often in males. Affected females are more likely to present primarily with inattentive features.

ADHD occurs and can be diagnosed in the toddler (although the false-positive rate is relatively high). The diagnosis is more reliably made when a child reaches 4 years old. Hyperactive and impulsive symptoms typically increase during the next 3 to 4 years, peaking at age 7 to 8 years. By adolescence, hyperactivity symptoms diminish, although symptoms of impulsivity and feelings of restlessness persist. Symptoms of inattention usually are not obvious until the child is 8 to 9 years old. ADHD persists into adulthood in two-thirds to three-fourths of people diagnosed with ADHD in childhood.

Attention disorders (with or without hyperactivity) are diagnosed based on history obtained from parents, observations of the child, questionnaires from parents and teachers, and in some instances, computerized tests of attention. As the disorder must affect functioning in at least two settings (school, after school, or home), it is advisable to obtain some written or verbal report from the child's teacher or school personnel. Given the high rate of psychiatric comorbidities in ADHD (eg, anxiety and mood disorders, oppositional defiant disorder, conduct disorder), both narrowband questionnaires that specifically assess for ADHD and broadband questionnaires that assess for ADHD as well as other psychiatric comorbidities should be used. The elemental neurologic examination is generally normal, although minor findings are common (eg, synkinesis during repetitive finger tapping and sequencing tasks). Neuropsychological testing is not absolutely necessary unless comorbid learning disabilities are suspected. The neuropsychological profile usually reveals average intelligence, but low scores are common on the Wechsler IQ subtests that demand attention or rapid processing (eg, digit span, coding, arithmetic, symbol search) and intratest scatter often is found, reflecting variability in attention. Executive frontal lobe functioning—the ability to initiate, inhibit, sustain, and shift attention; working memory; and organizational skills—is often impaired.

ADHD has a substantial genetic component. Reported concordance of ADHD in identical twins ranges from 0.70 to 0.88. ADHD frequently co-occurs with other neurobehavioral disorders such as Tourette syndrome, obsessive-compulsive disorder, anxiety, and learning disabilities, raising the question of possible shared susceptibility genes.

Dopamine appears to be the primary neurotransmitter involved in ADHD. Medications that increase levels of dopamine, in particular psychostimulants, are the mainstay of treatment. The National Institutes of Health–sponsored Multimodal Treatment Study of ADHD has shown both behaviorally and by neuropsychological testing that stimulants work and that they work better than behavioral modification LEVEL 1.[1] Approximately, 75% of children respond to stimulants initially. Side effects may limit treatment (eg, weight loss, rebound depression or irritability, flat affect) in 5% to 10%. Many different formulations of the stimulants exist, with different durations of action. Tics are not a contraindication to stimulant use in ADHD, although they may affect medication choices. Comorbid mood or anxiety disorders also influence medication choice. Medications other than stimulants can also be used to treat ADHD. Atomoxetine (starting dose: 0.5 mg/kg every day) and α-agonists clonidine (starting dose: 0.05-0.1 mg every day), guanfacine (starting dose: 0.5-1 mg every day), Intuniv (starting dose: 1 mg every day), and Kapvay (starting dose: 0.1 mg at bedtime) are accepted nonstimulant medication choices. Tricyclic antidepressants, selective

serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, bupropion, and modafinil have all been used but generally only in those who failed to respond to stimulants. In addition to medication, treatment should focus on parent skills training, educational accommodations (preferential seating, extended time/separate testing site for testing, organizational supports), and behavioral modification.

Autism Spectrum Disorders 143

Sylvie Goldman and Jennifer M. Bain

KEY POINTS

1. Autism spectrum disorders (ASD) are a common neurodevelopmental disorder, behaviorally defined by deficits in social interaction and communication and the presence of restricted and repetitive patterns of behavior, interests, and activities and sensory atypicalities.
2. Genetics plays a large role in the pathophysiology of ASD and should be included in the workup of an individual with ASD.
3. Seizures are more common in ASD than the general population; therefore, there should be a low threshold to use electroencephalogram monitoring.
4. There is no indication for brain imaging or metabolic workup in most cases of autism.
5. Medical comorbidities are common in ASD and should be screened routinely especially when behavioral changes emerge.

INTRODUCTION

Autism spectrum disorders (ASDs) are a heterogeneous group of biologically based, behaviorally defined, neurodevelopmental disorders characterized by core symptoms of impairments in (1) social communication and social interactions and (2) restricted and repetitive patterns of behavior, interests, and activities and sensory atypicalities. The term *autism* (originating from the Greek word *autos* meaning *self*) was adopted for the first time in 1911 by Eugen Bleuler, a Swiss psychiatrist, to refer to a group of symptoms related to schizophrenia. Leo Kanner later used the term *autism* in 1943 to describe children whose behavior was "governed rigidly and consistently by the powerful desire for aloneness and sameness."

The ASDs have been defined in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) of the American Psychiatric Association. The initial diagnosis of *classic autism* or *early infantile autism* was described in the *DSM-II* (1968) as a form of childhood schizophrenia marked by a detachment from reality, whereas *DSM-III* broadened the concept by adding a diagnosis at the mild end of the spectrum referred to as *pervasive developmental disorder–not otherwise specified* (PDD-NOS). The *DSM-IV* and *DSM-IV-TR* further broadened this spectrum by adding the higher functioning Asperger disorder and regressive phenotype of childhood disintegrative disorder. The most recent revision in 2013 is *DSM-5* where ASD combines the separate diagnostic categories of autistic disorder, PDD-NOS, and Asperger syndrome. These changes are based on research results, which have failed to document these categories as separate biologic entities. Recent meta-analyses have confirmed stability or even decreased rates of diagnoses with this single diagnostic entity as compared to the individual diagnoses under *DSM-IV-TR*.

Under the *DSM-5*, ASD diagnosis requires three deficits in social communication and at least two symptoms in the category of restricted range of activities/repetitive behaviors that have been identified from an early age. Deficits in language have been removed as a separate criterion and are now included in the social and communication diagnostic criteria. Another important change in the *DSM-5* is the additional category of abnormal sensory symptoms. The *DSM-5* specifies three levels of severity (mild, moderate, severe), rated separately for each domain. In addition to the diagnosis, individuals are also described in terms of level of language and intellectual disability, any known genetic cause (eg, fragile X syndrome, Rett syndrome) and presence of medical conditions such as seizures, psychiatric disorders (eg, anxiety, depression), and/or gastrointestinal disorders. The variability in severity and range of disabilities seen in children with ASD cannot be overemphasized.

EPIDEMIOLOGY

The prevalence of ASD has increased significantly particularly since the late 1990s when the estimated frequency was about 1 per 1,000 for autism and 2.8 per 1,000 for all ASD subtypes (autistic disorder, Asperger syndrome, and PDD-NOS). Since 2000, the Centers for Disease Control and Prevention supports ASD surveillance via the Autism and Developmental Disabilities Monitoring Network by identifying ASD through screening and review of health and education records and documents behaviors associated with ASD at various U.S. sites. The most recently reported prevalence rate of 16.8 per 1,000 (1 in 59) among 8-year-olds, with prevalence estimates varying from 13.1 to 29.3 per 1,000 across the different sites (2014). Early monitoring of 4-year-olds in the early Autism and Developmental Disabilities Monitoring cohort has shown that a diagnosis of autism at age 2 years can be reliable, valid, and stable and encourages providers to make earlier diagnoses for referral for treatment. Non-Hispanic white children were approximately 30% more likely to be identified with ASD than non-Hispanic black children and almost 50% more than Hispanic children. The ASDs are diagnosed 4 times more likely in males than in females; however, studies report that many girls have been missed or diagnosed later due to the clinical male-biased approach and male-based instruments. The recent emphasis and recognition of a female phenotype for ASD is helping to lower the age of diagnosis for girls.

The overall increase of ASD prevalence may be related to several factors, most notably changes in diagnostic criteria, broadening of the definition with an emphasis on heterogeneity, co-morbidity, and inclusion of mildly affected individuals. There is also increased awareness among parents and professionals, especially with increased media attention. Changes in legislation and insurance mandates have also transformed the negatively stigmatizing

diagnosis of ASD into a somewhat more favorable diagnosis providing robust, comprehensive interventions. There remains variability between states in level and comprehensiveness of services.

PATHOBIOLOGY

Genetics

The ASDs are clinically and etiologically heterogeneous; genetic identification may provide stratification for anticipatory guidance and clinical trials. Twin and family studies provide evidence for ASD as a genetically based disorder with heritability estimates of 85% to 92%. Genetic heterogeneity is suspected. Using currently available technology, a genetic cause can be identified in up to 30% to 40% of children with ASD, whereas some studies argue the percentage is much higher. The proportion of cases with genetic etiology increases with additional comorbidities such as intellectual disability and epilepsy.

Known genetic causes of ASD include cytogenetic visible chromosomal abnormalities, copy number variants (CNVs) (eg, submicroscopic deletions and duplications), and single-gene disorders in which neurologic findings are associated with ASD. For both chromosomal microarrays (CMAs) and whole exome sequencing, it continues to be difficult to establish whether variants are pathogenic or benign; therefore, continued research is essential for newly identified variants. Parental testing is frequently performed to assist in interpretation of abnormal findings. Informed genetic counseling is critical in this process, and children identified with variants of unclear significance should be followed periodically by the geneticist to identify any new information that be shared with them.

The CMA is rapidly replacing high-resolution chromosomes as the initial test of choice to evaluate children with ASD. The CMA has identified clinically relevant de novo genetic imbalances in up to 20% of individuals with autism of unknown cause. The most common autism-related CNVs are the 15q11.2-11.3 duplications, reciprocal 16p11.2 microdeletions and duplications, and the 7q11.23 duplication (**Table 143.1**). Recent estimates are that CNVs that contain multiple contiguous genes may confer susceptibility to ASD in up to 8% to 9% of individuals. It should be noted that CMA will not detect balanced translocations or low-level mosaicism; a karyotype should be done when there is a family history of multiple miscarriages or there is high suspicion of mosaic aneuploidy.

Fragile X DNA testing remains essential in the evaluation of ASD because it is the most common single gene cause of autism. Approximately 1% to 3% of patients with ASD will have a mutation in the fragile X mental retardation 1 gene while approximately 60% of males and 20% of females with fragile X syndrome also meet criteria for ASD.

Identification of single-gene disorders as potential etiologies continues to grow. The list of autism "risk genes" continues to grow into the hundreds (see **Table 143.1**). Methods used include both large genome-wide association studies and whole exome sequencing of large autism databases. Instead of identifying specific genes, grouping based on function is currently used to better categorize these single genes. For example, neuroligin 3 and 4, neurexin 1, contactin 4, contactin-associated protein-like 2, and SHANK3 all play roles in synapse formation and function. The mammalian target of rapamycin (mTOR) signaling pathway also contains many ASD risk genes including *TSC1*, *TSC2*, *PTEN*, and *NF1*. Other genes have roles in splicing and posttranscriptional regulation, DNA methylation and chromatin remodeling, and other transcription factors. This area is rapidly evolving especially as large remote access autism databases grow such as SPARK for Autism (Simons Foundation) and Google's MSSNG.

Genetic stratification provides more insight into the pathophysiology of autism, establishes homogenous cohorts for precision medicine clinical trials, and provides targeted information about anticipatory guidance and information for family planning. Lastly, identification of ASD as related to an overarching genetic syndrome can allow clinicians to screen for potential medical comorbidities associated with this syndrome such as those associated with higher incidences of epilepsy, which would warrant electroencephalogram (EEG) monitoring.

The strong evidence that supports a genetic etiology for ASD has led researchers to develop the high-risk sibling cohorts referred as *Baby Siblings Research Consortium (BSRC) studies*, defined as groups of children who have an older sibling with a confirmed diagnosis of ASD. These studies provide insights into the very early presentation of ASD. For example, the Baby Siblings Research Consortium follows infants from high familial risk for autism and focuses on specific skills or traits to identify biomarkers for earlier autism diagnosis. For example, early motor skills and language development, especially receptive language and specific EEG patterns as early as 3 months of age, were strong predictors of later ASD diagnosis.

Lastly, while the genetics in autism research is expanding exponentially, studies examining environmental influences continue to be investigated as additional factors, which may influence and trigger the development of ASD. Established environmental risk factors for ASD include prematurity, advanced parental age, maternal infections (such as rubella), gestational diabetes, and maternal medication use (notably valproic acid). Mounting evidence suggests that airborne toxins, including air pollution increased the risk of having a child with autism. However, it is important to note that the interactions between genetics and environment are still largely unknown. There is no scientific evidence that any vaccine, including measles-mumps-rubella cause autism.

Neuropathology

Studies of brain structure have implicated abnormalities in prenatal and postnatal brain development, particularly neuronal sequences and maturation. Prenatal imaging and postmortem study supports a prenatal onset of ASD, occurring during the second and third trimesters of pregnancy. The generalized enlargement of the brain resulting from premature overgrowth attests to the broadness of the involvement of the brain, precluding focal brain theories and single primary deficit theories. The occurrence of mutations in genes that

act on molecular signaling pathways involved in the development and maintenance of neuronal and synaptic connections, notably with pruning, have reinforced the centrality of disruption of cortical growth and connectivity in ASD.

The most consistent abnormality seen on neuroimaging studies and in postmortem examination is increased brain weight and volume in children with ASDs compared to controls. Very young children with ASD (18 mo to 4 y) have a 5% to 10% increase in brain volume, especially in the frontal lobes, which parallels the increasing head circumference during this period. By adolescence and adulthood, however, brain volumes seem to be lower than in controls, suggesting brain overgrowth within the first few years of life is followed by potential neurodegeneration. Imaging studies also highlight other anatomic abnormalities noted in other brain regions, including the cerebellum, hippocampus, and basal ganglia. Increased brain volume in childhood is attributed primarily to enlargement of white matter, specifically the corona radiata and U-fibers, whereas the size of the corpus callosum is reduced, perhaps resulting in decreased interhemispheric communication. These white matter and connectivity abnormalities are still largely under investigation. Magnetic resonance spectroscopy studies suggest that gray matter is abnormal and dendritic arborization and synaptosome density reduced with lower levels of neuronal *N*-acetylaspartate and alterations in choline and creatinine metabolism. Emerging research supports abnormal gyrification patterns in individuals with ASDs at various time points of development. Other brain imaging techniques under investigation are positron emission tomography and single-photon emission computed tomography, which suggest reduced brain perfusion and neurotransmitter abnormalities. Functional imaging studies (functional magnetic resonance imaging) have shown atypical patterns of brain activation during tasks of face processing, language, and emotional understanding. Activation of the mirror neuron system—a network within the inferior frontal gyrus and posterior parietal lobe that is thought to subserve imitation and understanding of intentions of other people—is reduced in individuals with ASDs, suggesting a role for this network in autism. Focal patches of abnormal laminar cytoarchitecture and cortical disorganization of neurons, but not glia, have suggested a dysregulation of layer formation and neuronal differentiation prenatally. Efforts by organizations such as the *Autism Brain Net* brain bank hope to safely secure more postmortem tissue for future studies.

DIAGNOSIS

With no biomarkers available, the diagnosis of ASD relies solely on detailed clinical observation and developmental history (Fig. 143.1). Even though most symptoms of ASD can be identified reliably between 18 and 24 months, most children are diagnosed around age 4 years and many are still misdiagnosed with language delays or anxiety. Consequently, a major emphasis has been on early diagnosis using a cohort of high-risk siblings (BSRC) described earlier. Infants with an older sibling who carries a diagnosis of ASD are enrolled in longitudinal studies starting in early infancy before traits can be confirmed. Specific target behaviors, called *predictors*, include facial recognition, eye gaze, and motor milestones.

Social communication dysfunction, the hallmark of ASDs, can take many forms from avoidance and aloofness to excessive friendliness. Early signs of social impairments include failure to respond to name, reduced initiation, abnormal eye gaze (gaze aversion, staring), paucity of communicative gestures, lack of reciprocity, poor imitation, and impairment of joint attention defined as the ability to draw another person's attention to an object of interest through coordinated eye gaze and gestures such as pointing. Children with ASD interact with others to fulfill their own needs (self-directed) rather than to share their interests, enjoyment, and achievements.

Another cardinal feature of ASD is a restricted range of interests and activities that take the form of repetitive, patterned, and often rhythmic behaviors. These include sound or word repetition and motor stereotypies such as hand flapping, finger flicking, spinning, throwing, or body rocking. These repetitive behaviors may also involve specific sensory modalities such as smelling, licking, or looking from the corner of the eyes. This category also encompasses unusual preoccupations and play interests such as a focus on details rather than the use of the whole toy for functional purpose (eg, spinning the plate rather than using it to pretend to feed the doll). Children with ASD may line up toys, flick doll's eyes, or play with unusual objects (eg, a piece of string) instead of engaging in imaginative play. Many children develop routines or rituals and a need for sameness or resistance to changes, which make transitions very difficult. Adults with ASD may be preoccupied by timetables, routes, or movies.

In addition to the previously revised diagnostic criteria for ASD, the *DSM-5* provides a new diagnostic category namely "Social Communication Disorder" intended to identify individuals who have significant problems in using verbal and nonverbal communication in social interactions and who do not exhibit repetitive, stereotyped behaviors, restricted interests or sensory anomalies.

Evaluation

The evaluation of a child with autism includes a detailed clinical history and observation of free and structured activities as well as a battery of parent questionnaires and standardized verbal, nonverbal, and motor tests. When feasible, a multidisciplinary team is the best approach. Indeed, experts argue that no single tool should be used to make a diagnosis of ASD. By age 2 years, a qualified professional should reliably be able to make the diagnosis. The American Academy of Pediatrics recommends screening all children at well-child visits at 18 months and at 24 months of age. A number of questionnaires and observation measures are available to screen for ASD such as the Modified Checklist for Autism in Toddlers-Revised between 18 and 36 months of age and the Social Communication Questionnaire or the Social Responsiveness Scale, 2nd edition, for older children. The Autism Diagnostic Observation Schedule-2 (ADOS-2) is considered the "gold standard" diagnostic instrument for ASD. It consists of a semistructured, standardized assessment of social interaction, play, and imaginative use of material for toddlers through adults using different modules. The ADOS-2 is often used in conjunction with the Autism Diagnostic Interview-Revised (ADI-R), a clinical diagnostic interview focusing on early social and repetitive behaviors. Both the ADOS-2 and ADI-R require special training to administer and score. Other well-known assessments include the Childhood Autism Rating Scale, 2nd edition, and the Gilliam Autism Rating Scale, 3rd edition, for which teachers, parents, and clinicians provide a rating of specific diagnostic behaviors.

Neurologic Examination

Observations of the child are the key components of the neurologic examination. Head circumference should be measured because macrocephaly, defined as greater than 2.5 standard deviations above the mean or 98% for age, has been observed in some children

FIGURE 143.1 *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, criteria of autism spectrum disorder and associated comorbidities.

with ASD. Microcephaly may be more suggestive of a developmental brain injury such as hypoxic ischemic encephalopathy, in utero infection such as TORCH infection or a specific genetic disorder. The skin examination requires careful attention, especially given the high co-occurrence with tuberous sclerosis and other neurocutaneous syndromes. Identification of dysmorphic features is important for making genetic diagnoses (eg, fragile X, velocardiofacial syndrome, and Smith-Magenis syndrome). Facial recognition software may provide clues for syndromic diagnoses. Motor findings may include mild hypotonia and/or motor apraxia. Toe walking and motor stereotypies are very common. Abnormal motor features are not considered as diagnostic criteria but are observed in more than 85% of individuals with ASD and are the earliest reliable predictor of a later ASD diagnosis among high-risk siblings of children with ASD. Early motor delays in head lag and postural control within the first 18 months, and delayed emergence of advanced postures such as kneeling or standing in high-risk children between 6 and 14 months of age are noted in children who later receive an autism diagnosis. With the advent of wearable technologies, gait analysis, in particular, has proven useful to measure these motor abnormalities.

Many children have a constellation of symptoms that are referred to as *sensory deficits*; however, the neurologic basis for this is unclear. These include a preoccupation with sensory features of objects, over- or underresponsiveness to environmental stimuli, or paradoxical responses to sensory stimuli (eg, excessive sniffing or licking, oral aversions, intolerant to loud noises, or tactile contact).

Cognition and Language

Large variations in intellectual functioning contribute to the challenge of diagnosing and treating ASD. Although intelligence is not a defining feature of ASD, it strongly influences prognosis and treatment response (children with IQs in the moderately to severely delayed range have poorer outcomes). Current estimates report intellectual disability (IQ <70) in approximately 31% of individuals with ASD. Savant skills can be seen in visuospatial ability, rote memory, calculation, or music ability but remain rare. Attention deficit hyperactivity disorder (ADHD) is a common comorbidity with ASD. In addition to overall cognitive disabilities and scattered skills, executive functions (eg, organization, planning, inhibition,

and working memory) and attention control (eg, hyper focus and lack of shifting) are commonly affected, whereas sustained attention is relatively spared.

Three unresolved issues need to be mentioned: (1) diagnosing ASD in individuals with very low IQ, (2) evaluation of IQ in severely affected individuals, and (3) cognitive/behavioral regression. Autism diagnostic tools are not designed for individuals with a mental age below 12 months, and thus, the controversy remains as to what extent an ASD diagnosis is applicable in very cognitively impaired individuals. Similarly, individuals severely affected by ASD symptoms with significant mood dysregulation, absence of language, and rigid behaviors may not perform to the full extent of their true cognitive abilities and may be wrongly classified. For example, techniques using eye tracking instead of verbal responses in individuals with Rett syndrome (with and without ASD) may be a promising alternative techniques to common IQ tests. Developmental regression or loss of previously acquired skills during the first 1 to 3 years of life has been reported in approximately one-third of children with ASD. There is an ongoing debate as to whether children experienced a true loss of skills versus a decline in premorbid developmentally delayed children. Regressions are difficult to capture and to document in a timely and reliable way, so ancillary sources such as home videos may be used as objective evidence. Clinical studies report that, overall, children who present a history of loss of skills have poorer outcome compared to children who did not.

Although no longer a criterion for a diagnosis of ASD, language disorder is highly prevalent and may include expressive, receptive, and pragmatic deficits. Language skills are often considered as outcome predictor especially for children who do not develop any language (minimally verbal or nonverbal). In fact, the most common parental concern in ASD clinics is language delay; an estimated 30% of individuals with ASD are minimally verbal or nonverbal. As opposed to children with language disorder without ASD, children with ASD do not compensate for their language impairment through nonverbal strategies such as gestures, facial expressions, or imitation. Their expressive language is characterized by immediate and delayed echolalia with repetitive and stereotyped phrases. Some children will use scripts from television or videos. Other abnormalities include syntax (word order, gender errors, rules of grammar), semantics (word meaning), and pragmatics skills (use of language for communication). Low and higher functioning individuals are extremely literal and concrete and often have difficulties understanding jokes, humor, or sarcasm. Speech prosody (melody of language) is impaired, as evidenced by mechanical, monotonous, excessively rapid, high-pitched, or dysregulated volume speech. Children with ASD often express more than what they can understand (receptive language), which differentiates them from language-impaired children without ASD. In the past, many children with ASD were misdiagnosed with deafness before it could be established that their hearing was normal. A small proportion of children with severe ASD, despite normal hearing, present with a significant auditory language processing disorder, which prevents them from decoding language into meaningful words (verbal auditory agnosia). Some children have a fascination with letters and numbers in the early toddler years, and some may learn to read without instruction, for example, hyperlexia, although overall comprehension is often limited. As children age, narrative skills become impaired with difficulty interpreting and reciprocating social and emotional cues. These individuals may use pedantic speech to tell simple events and usually talk only about topics of their own interest while being oblivious of the listener's interest, need for clarification, or even presence. Their conversations sound more like a monologue with a fixed intonation rather than a true dialogue. They often fail to maintain appropriate interpersonal distance and are unthinkingly intrusive or persistent. They also have poor nonverbal communication such as particular difficulty reading facial expressions, body language, social cues, and change of tone of voice.

Medical and Psychiatric Comorbidities

Medical comorbidities frequently exist in ASD. Examples of commonly associated medical conditions include, but are not limited to, pain (due to migraine headaches, dental caries, ear infection, fractures, constipation, etc), gastrointestinal disorders (eg, gastroesophageal reflux disease, constipation), genitourinary conditions (eg, urinary tract infection), hormonal imbalance/endocrine dysfunction (eg, menstruation), and sleep disturbance (eg, sleep apnea). Other neuropsychiatric disorders are more highly prevalent in ASD, including epilepsy, sleep disorders, and psychiatric conditions anxiety, depression, obsessive-compulsive disorder, ADHD, and self-injurious behaviors. It is important to consider medical causes for any change in behavior, especially in those individuals who are nonverbal or with limited language capability.

Epilepsy

Individuals with ASD have a higher risk of epilepsy compared with the general population. Epilepsy occurs in up to one-third of individuals with ASD with reports ranging from 5% to 50%. Variation in estimates is likely related to multiple factors such as sample ascertainment, degree of intellectual disability, age, gender, and type of ASD (idiopathic vs syndromic). Some of the most widely recognized syndromes associated with ASD and epilepsy include tuberous sclerosis, fragile X syndrome, Rett syndrome, Angelman syndrome, and 15q duplication syndrome. Intellectual disability and motor impairments (eg, cerebral palsy) have been identified most commonly as significant risk factors for epilepsy in ASD. Rates are higher in those with more severe cognitive impairments.

Age of onset of epilepsy in ASD generally appears in two peaks, one in early childhood (0-5 y) and the other in adolescence (10-15 y). The peak before age 5 years, however, includes those children with ASD secondary to epileptic spasms, tuberous sclerosis, and other epileptic encephalopathies.

Given the prevalence of epilepsy in autism, it is important to consider the possibility of seizures when evaluating an individual with autism. Currently, there is inadequate evidence to recommend EEG in all individuals with autism; however, the physician should have a low threshold for ordering an EEG. Although all seizure types can occur in ASD, the most commonly observed are complex partial seizures (85%) and generalized tonic-clonic seizures (7%). Absence and myoclonic seizures occur less commonly (1%-4%). The assessment for medical comorbidities that mimic seizures should include sleep disorders, gastroesophageal reflux and other gastrointestinal disorders, and behavioral disorders including ADHD.

Epileptiform EEG abnormalities are frequently seen in children with ASD, with or without epilepsy. Because these background or epileptiform EEG abnormalities can occur in ASD individuals without a clinical history of seizures, they are not to be considered evidence for epilepsy. The significance of these abnormalities, especially in the absence of clinical seizures, remains unclear. At present, there are no data to support the use of

antiepileptic drugs or epilepsy surgery in the treatment of EEG abnormalities in the absence of clinical seizures.

The relationship of autistic regression to epilepsy and epileptiform EEG abnormalities is also unclear. The literature is inconsistent with some studies reporting higher rates of epilepsy in children with ASD and regression and others showing no relationship. However, language regression is a hallmark of Landau-Kleffner syndrome (LKS), a rare childhood-onset epileptic encephalopathy in which loss of previously acquired language skills occurs in the context of an epileptiform EEG, activated in sleep. Electrical status epilepticus during slow-wave sleep (ESES) is the electroencephalographic pattern seen in LKS. The degree of overlap between LKS, ESES, and autistic regression with epileptiform EEG is currently poorly understood, although ESES is rarely seen in children with a more global autistic regression. At the current time, there are no data to support the use of LKS- or ESES-specific treatment regimens in those with more classic autistic regression and epileptiform EEG without clinical seizures.

Neurodiagnostic Testing

All children with ASD should have a comprehensive medical/pediatric history and examination. Neurodiagnostic testing can potentially identify any diagnosable or treatable condition. Hearing impairment must be excluded by a formal audiology assessment. Clinical practice guidelines recommend genetic testing but other diagnostic investigations such as neuroimaging, EEGs, or metabolic laboratory investigations follow "best practice" evidence-based guidelines when available. As mentioned earlier, CMA and fragile X are considered first-tier testing in the diagnostic workup of ASD (Table 143.1). The MECP2 sequencing for Rett syndrome and phosphatase and tensin homolog testing for those with head circumferences greater than 2.5 standard deviation above the mean are recommended second-tier testing. See Table 143.2 for genetic disorders associated with an ASD phenotype. The EEG, including a sleep record or overnight video-EEG monitoring, is appropriate when seizures occur or if developmental regression has occurred (see "Epilepsy" section).

TABLE 143.2 Genetic Disorders Associated With Autism Spectrum Disorders

Single-Gene Disorders	Cytogenetically Visible Chromosomal Abnormalities	Copy Number Variants (CNVs)
Fragile X	15q duplication syndrome	15q11.2-11.3 duplications
PTEN macrocephaly syndrome	Trisomy 21	Reciprocal 16p11.2 microdeletions and duplications

TABLE 143.3 Red Flags That Might Indicate a Metabolic Etiology for Autism Spectrum Disorders[a]

History or *Symptoms*	*Physical* or *Laboratory* Findings
• Active or recurrent regression • Profound intellectual disability or global developmental delay • Severe growth retardation • Deafness • Unexplained intractable seizures • Fatigue with daily activities or exercise • Recurrent or relapsing history of decompensation with illness • Family history suggestive of metabolic disease	• Objective neurologic abnormalities (eg, significant hypotonia with gross motor delay, muscle weakness, microcephaly, macrocephaly, dystonia/chorea) • Multiple organ system involvement • Unrelated signs suggesting an inborn error of metabolism (eg, hypoglycemia, metabolic acidemia) • MRI abnormality suggestive of metabolic disease

Abbreviation: MRI, magnetic resonance imaging.
[a]List is not meant to be exhaustive.

Only 1% of patients with autism have an underlying metabolic disorder. There are multiple metabolic causes of ASD, many of which are not usually associated with any dysmorphology. A careful history and examination often identifies "red flags" that increases a concern for an inborn error of metabolism (Tables 143.3 and 143.4). Treatable conditions include phenylketonuria, hyperammonemia/urea cycle defects, and creatine synthesis/creatine transporter defects. Primary mitochondrial disease and ASD is a subject of much debate. Some investigators report a significant incidence of mitochondrial DNA changes or functional disturbances in children with ASD. Whether these are the primary cause of ASD remains to be defined. The extent of the evaluation for an underlying metabolic disorder depends on clinical suspicion and the relevance to family counseling.

The clinical rationale for neuroimaging in children with ASD is an attempt to determine a specific etiopathologic diagnosis for an individual. In a minority of cases, the detection of an abnormality of the brain may lead to determination of a specific cause for the child's ASD. This is true especially if the lesion is pathognomonic for a given disorder, for example, a neurocutaneous syndrome such as tuberous sclerosis complex. However, in many cases, the etiology of the brain abnormality is still unknown and the relationship to the ASD unclear. Nonetheless, the magnetic resonance imaging may help guide more focused etiologic investigations that could further lead to specific diagnoses in a limited number of cases. Sedation for

TABLE 143.5 Clinical Indicators That Might Prompt Neuroimaging With Brain Magnetic Resonance Imaging

• Seizures or history of focal EEG
• Microcephaly
• Extreme (>3 SD above mean) or progressive macrocephaly
• Neurocutaneous lesions
• Suspicion of CNS structural abnormality
• Focal motor findings or a change in motor examination
• Active or recurrent regression

Abbreviations: CNS, central nervous system; EEG, electroencephalogram; SD, standard deviation.

this procedure must be carefully weighed by the clinician. For these reasons, imaging is not a routine part of the evaluation of individuals with ASD in the absence of "red flags" (**Table 143.5**).

MANAGEMENT

There are no known cures for ASDs; however, early intensive behavioral and educational interventions are the most effective evidence-based intervention for treating ASD core symptoms in ASD. Children with ASD often require many hours of multiple therapies along with parent support.

Behavioral interventions may include applied behavior analysis based on response reinforcement and the Treatment and Education of Autistic and Related Communication-Handicapped Children method using structured teaching. Functional behavioral analysis is an important evaluation tool to identify the antecedents, consequences, and functions of behaviors. So far, applied behavior analysis therapy remains the only evidence-based treatment and shows best results to alleviate maladaptive and challenging behaviors such avoidance, aggression, and self-injurious behaviors. These behaviors may require psychopharmacologic treatment and exclusion of medical causes.

After many years of damaging irrational theories about the mother's role in ASD, the field has finally recognized parental involvement as a central part of the treatment program. Thus, newer approaches include Developmental, Individual Difference, Relationship approach (DIR/Floortime) based on social relationships; the Early Start Denver Model a combination of developmental and relationship-based interventions; Parent-mediated social Communication Therapy; and Joint Attention, Symbolic Play, Engagement and Regulation treatment and approach. Social skills training is also important for older and higher functioning individuals with ASD. Caregiver and family involvement continues to be integral in most behavioral programs.

A combined approach of pharmacotherapy and behavioral modification therapy is often necessary. The only U.S. Food and Drug Administration–approved medications specifically indicated for autism-related concerns are aripiprazole and risperidone for ASD-associated irritability and aggression. However, other medications are commonly used to treat comorbid symptoms/conditions such as inattention, hyperactivity/impulsivity, obsessive-compulsive disorder, anxiety, depression, sleep disturbance, and seizures. The effects of pharmacologic interventions are enhanced by behaviorally based programs. Clinical investigations continue to study the efficacy of medications on social deficits.

OUTCOME

The ASD is a lifelong disorder and symptoms often change with age. Families must be supported during transitions to adolescence and adulthood. Decisions about guardianship should be made prior to running 18 years of age. Support groups and advocacy groups may provide guidance during these transition periods.

Outcome studies of children diagnosed with ASD suggest that although 40% show overall improvement during adolescence, as many as a third may deteriorate. The onset of seizures may contribute to this decline. Approximately, two-thirds of adults with autism show poor social adjustment (limited independence in social relations) and half require institutionalization. In addition, psychiatric comorbidities commonly develop in adolescence and adulthood: depression, anxiety, catatonia, and schizophrenia.

Although ASD are considered lifelong, recent literature suggests that a minority of individuals with ASD may not fulfill diagnostic criteria after middle childhood and are considered "optimal outcome." These older children may be functioning within the nonautistic range of social interaction and communication with subtle social and communication difficulties (such as personal narratives) and mild residual restricted and repetitive behaviors. Early motor skills may be predictive of optimal outcome.

144 Mitochondrial Encephalomyopathies

Salvatore DiMauro, Emanuele Barca, and Michio Hirano

KEY POINTS

1. In addition to generation of adenosine triphosphate energy via oxidative phosphorylation, mitochondria perform multiple additional functions, which can be disrupted and cause a variety of human diseases.
2. Common clinical features of mitochondrial disease include multisystemic involvement (eg, three or more affected organs), encephalomyopathies, chronic progressive external ophthalmoplegia, and Leigh syndrome.
3. The key principles of mitochondrial point mutations are (1) maternal inheritance, (2) mitochondrial DNA (mtDNA) heteroplasmy, (3) threshold effect, and (4) tissue distribution. These factors affect the clinical phenotypes of mtDNA mutations.
4. In addition to maternally inherited mitochondrial diseases, there are sporadic disorders (eg, Kearns-Sayre syndrome typically caused by spontaneous single large-scale mtDNA deletions) as well as autosomal dominant, autosomal recessive, and X-linked diseases.
5. Mitochondrial diseases can affect individuals at any age from birth through late adulthood.

TABLE 144.1 Genetic Classification of Mitochondrial Diseases With Representative Clinical Syndromes

1. **Defects of mitochondrial DNA**
   - A. Single deletions (usually sporadic)
     - i. Kearns-Sayre syndrome
     - ii. Chronic progressive external ophthalmoplegia (CPEO) and CPEO-plus
     - iii. Pearson syndrome
   - B. Point mutations (maternal transmission)
     - i. Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes
     - ii. Myoclonus epilepsy with ragged red fibers
     - iii. Leber hereditary optic neuropathy
     - iv. Neuropathy, ataxia, and retinitis pigmentosa
2. **Defects of nuclear DNA (mendelian or X-linked transmission)**
   - A. "Direct hits": mutations in genes encoding subunits of the respiratory chain enzyme complexes with biochemical defects of complex I, II, III, or IV presenting as Leigh syndrome or a multisystemic disorder
   - B. "Indirect hits": defects of respiratory chain enzyme complex assembly factors with biochemical defects of complex I, II, III, or IV presenting as Leigh syndrome or a multisystemic disorder
   - C. Defects of mitochondrial transcription
   - D. Defects of mitochondrial translation
   - E. Defects of mitochondrial lipid composition
   - F. Defects of mitochondrial dynamics (fusion, fission, movement)
   - G. Defects of mitochondrial DNA maintenance
   - H. Defects of mitochondrial importation
   - I. Defects of mitochondrial metal metabolism

INTRODUCTION

Mitochondria are uniquely intriguing organelles not only for the variety of biologic functions that they perform but also because of their regulation by two genomes—their own DNA (mitochondrial DNA [mtDNA]) and that of the nucleus (nDNA). Accordingly, mitochondrial diseases can be due to mutations in either genome (Table 144.1). The main function of mitochondria is aerobic production of adenosine triphosphate (ATP) energy through oxidative phosphorylation (OxPhos). Because brain and muscle have high-energy requirements, mitochondrial disorders frequently manifest as encephalomyopathies. Advances in this rapidly expanding field have been covered extensively in recent reviews, but here we provide general overview of the genetically and clinically heterogeneous mitochondrial diseases.

In 1962, the first human disease attributed to mitochondrial dysfunction was described as a hypermetabolic state in a patient with normal thyroid function and excessive number of abnormally large mitochondria in skeletal muscle. Biochemical studies showed "loose coupling" of OxPhos. This syndrome was named after the endocrinologist Rolf Luft. Since then, however, there has been only one other known case of Luft syndrome and its etiology remains unknown.

Later in the 1960s, mitochondrial diseases were brought to prominence by Milton Shy and Nicholas Gonatas, who defined this new organellar disorder by the electron microscopic appearance of overabundant or enlarged mitochondria with paracrystalline inclusions. Soon thereafter, W. King Engel noted that abnormal proliferation of mitochondria could be identified under the light microscope as *ragged red fibers* (RRF) with a modified Gomori trichrome stain. For the next two decades, this histologic hallmark was the basis for recognition of mitochondrial diseases based on an initial biochemical classification.

The molecular era of mitochondrial disease began in 1988 when the first two pathogenic mutations in mtDNA were described: a point mutation in Leber hereditary optic neuropathy (LHON) patients and single large deletions causing mitochondrial myopathy.

EPIDEMIOLOGY

Although mitochondrial diseases have been detected worldwide, epidemiologic data are limited. The prevalence of mitochondrial disease in the pediatric population (younger than 18 y old) has

been estimated to be 5 to 15 per 100,000 across various regions of Europe, Australia, and Japan. In the North East of England, the prevalence of mitochondrial disease in adults (older than 16 y old) has been estimated to be 12.5 per 100,000.

PATHOBIOLOGY

We consider separately the pathobiology associated with mtDNA mutations and with nDNA mutations.

Pathobiology of mtDNA Mutations: Mitochondrial Genetics Versus Mendelian Inheritance

Human mtDNA is a small (16.6 kb) circle of double-stranded DNA (Fig. 144.1) comprising only 37 genes. Of these, 13 encode polypeptides, all subunits of the OxPhos pathway: 7 subunits of complex I (nicotinamide adenine dinucleotide hydride [NADH]-ubiquinone oxidoreductase), 1 subunit of complex III (ubiquinone–cytochrome *c* oxidoreductase), 3 subunits of complex IV (cytochrome *c* oxidase [COX]), and 2 subunits of complex V (ATP synthase). The other 24 genes encode 22 transfer RNAs (tRNAs) and 2 ribosomal RNAs (rRNAs) that are required for translation of messenger RNAs on mitochondrial ribosomes (mitoribosomes). The subunits of complex II (succinate dehydrogenase [SDH]-ubiquinone oxidoreductase) and the enzymes required for synthesis of small electron carriers (coenzyme Q_{10} [CoQ_{10}] [ubiquinone] and cytochrome *c*) are encoded exclusively by nDNA.

The following main principles distinguish mitochondrial genetics from mendelian genetics and help explain many of the clinical peculiarities of mtDNA-related disorders.

1. *Polyplasmy*. Most cells contain multiple mitochondria and each mitochondrion contains multiple copies of mtDNA so that there are thousands of mitochondrial genomes in each cell.
2. *Heteroplasmy*. When an mtDNA pathogenic mutation affects some but not all genomes, a cell, a tissue, indeed a whole individual will harbor two populations of mtDNA, normal (or wild-type) and mutant, a condition known as *heteroplasmy*; in normal tissues, all mtDNA were considered identical, a situation called *homoplasmy*. However, highly sensitive next-generation sequencing has revealed the coexistence of mutated mtDNA variants (0.2%-2.0% heteroplasmy) and

FIGURE 144.1 The oxidative phosphorylation pathway **(top)** and mitochondrial DNA **(bottom)**. Genes and corresponding gene products are similarly color-coded. ND denotes the subunits of NADH-coenzyme Q (CoQ) oxidoreductase (complex I); cyt *b*, cytochrome *b*; subunits of cytochrome *c* oxidase (COX) are labeled CO in the mitochondrial DNA scheme and COX in the respiratory chain rendition; *A6* and *A8* indicate subunits 6 and 8 of adenosine triphosphate (ATP) synthase. The 22 transfer RNA genes are denoted by one-letter amino acid nomenclature, whereas *12S* and *16S* denote ribosomal RNAs. O_H and O_L are the origin of heavy- and light-strand replication; heavy strand promoter (HSP) and light strand promoter (LSP) are the promoters of heavy- and light-strand transcription. Abbreviations: ADP, adenosine diphosphate; cyt *c*, cytochrome *c*; H_2O, water; IMM, inner mitochondrial membrane; IMS, intermembrane space; MAT, matrix.

wild-type mtDNA within a cell in blood and skeletal muscle of clinically unaffected individuals (a phenomenon termed *universal heteroplasmy*).

3. *Threshold effect*. The functional impairment associated with a pathogenic mtDNA mutation is largely determined by the degree of heteroplasmy, and a minimal critical number of mutant genomes (the mutation load) is required before tissue dysfunction becomes evident (and related clinical signs become manifest), a concept aptly termed *threshold effect*. This is, however, a relative concept: Tissues with high metabolic demands, such as brain, heart, and muscle, tend to have lower tolerance for mtDNA mutations than do metabolically less active tissues.
4. *Mitotic segregation*. Both organellar division and mtDNA replication are apparently stochastic events unrelated to cell division: Thus, the number of mitochondria (and mtDNA) can vary not only in space (ie, among cells and tissues) but also in time (ie, during development or aging). Moreover, at cell division, the proportion of mutant mtDNAs in daughter cells may drift, allowing for relatively rapid changes in genotype; therefore, if and when the threshold is exceeded, a clinical phenotype may manifest.
5. *Maternal inheritance*. At fertilization, all mitochondria (and all mtDNA) in the zygote are derived from the oocyte. Therefore, a mother carrying an mtDNA pathogenic mutation will pass it on to all her children, males and females, but only her daughters will transmit to their progeny, in a vertical matrilineal line. There are, however, a few exceptional cases of paternal leakage of mtDNA into zygotes leading to biparental inheritance. When maternal inheritance is evident in a clinical setting, it provides strong evidence that an mtDNA mutation must underlie the disease in question. However, the other features of mitochondrial genetics (eg, heteroplasmy degree and the threshold effect) often mask maternal inheritance by causing striking intrafamilial clinical heterogeneity. Thus, when suspecting an mtDNA-related disorder, it is crucial to collect the family history meticulously, paying special attention to "soft signs" (such as short stature, hearing loss, or migraine headache) in potentially oligosymptomatic maternal relatives.

More than 270 point mutations of mtDNA have been identified (**Fig. 144.2**). Ten pathogenic mutations in mtDNA have been observed frequently in neonatal cord blood of over 3,000 well babies, and a surprisingly high frequency, 1 in 200, harbored a pathogenic mtDNA mutation. The frequent occurrence of mtDNA mutations leads to a correspondingly high prevalence of mtDNA-related diseases: In the northeast of England, for example, 1 in 10,000 people are clinically affected by mtDNA-related disorders, and 1 in 6,000 individuals are considered at risk.

Mendelian Inheritance

The identification of nDNA mutations for mitochondrial diseases has accelerated rapidly since the discovery in 1995 of the first "direct hit" mutation in an nDNA-encoded gene for one of four subunits of complex II, exclusively controlled by nuclear genetics. These advances have been made possible by rapidly evolving molecular genetic technologies, including next-generation genome-wide (whole exome) sequencing and mitochondrial disease panels encompassing subsets of the nDNA genes required for mitochondrial functions. The advantages of high-throughput DNA sequencing are eminently practical, enabling rapid diagnosis of puzzling cases and informing genetic counseling.

Direct Hits Mutations

"Direct hits" refer to pathogenic mutations that directly affect nDNA-encoded respiratory chain subunits in all five complexes but most commonly affecting the 22 of the 45 structural subunits of the gigantic complex I. A growing number of direct hits affect complex II, complex III, complex IV (COX), and complex V (ATP synthase). In keeping with the all-or-none effect of mostly recessive mendelian mutations, as opposed to the variegated effect of heteroplasmic mtDNA mutations, disorders to direct hits to the mitochondrial respiratory chain generally manifest at or soon after birth and are severe, often being lethal in infancy, most often associated with Leigh syndrome (LS).

Indirect Hits Mutations

Even when all nDNA-encoded subunits of the various complexes are expressed correctly, they must be translated, imported into mitochondria, and directed to the inner mitochondrial membrane (IMM). At this site, they assemble with their mtDNA-encoded counterparts, acquire prosthetic groups, if necessary multimerize, and further assemble into supercomplexes (respirasomes). Mutations in these pathways are referred to as *indirect hits*, as they indirectly affect the mitochondrial respiratory chain.

In 1998, the search for the molecular basis of COX-deficient LS led to simultaneous discovery by two groups of the first mutant mitochondrial assembly gene, *SURF1*. Mutations in SURF1 are among the most common causes of LS. Mutations in at least 14 more COX assembly factors have been associated with various human diseases, predominantly encephalopathy, but cardiopathy often occurs with some mutations (*SCO2*, *COX10*, *COX15*, and *COA5*), whereas hepatopathy is associated with the *SCO1* mutations.

In patients with complex I deficiencies that are difficult to define molecularly, mutant assembly factors have been identified through next-generation sequencing of DNA. The clinical manifestations of these indirect hits tend to be more clinically heterogeneous than those associated with direct hits; all described patients have had encephalopathy resembling LS, but many have had leukodystrophy rather than gray matter involvement. Cardiomyopathy is often the dominating feature, presenting in infancy or in early childhood and early death.

The first assembly defect in complex III was identified in 2002 in Finnish infants with an extremely severe syndrome named GRACILE, an acronym aptly summarizing the symptoms and signs: growth retardation, aminoaciduria, cholestasis, iron overload, and early death. The mutated protein was the mitochondrial chaperone BCSL1, needed for insertion of the iron-sulfur (Fe-S) subunit into complex III.

A new group of disorders attributed to deficiency of CoQ_{10} can be related to indirect hits that consist of mutations in a cascade of biosynthetic enzymes. They result in deficiency of this relatively simple component, CoQ_{10}, which is an integral part of the respirosome, where it shuttles electrons from complexes I and II to complex III, acts as an antioxidant, and modulates apoptosis. Molecular defects in genes encoding CoQ_{10} biosynthetic enzymes (*PDSS2* and *COQ2*) were initially discovered in 2006, but mutations in other biosynthetic genes (*PDSS1*, *COQ4*, *COQ5*, *COQ6*, *COQ7*, *ADCK3* [*COQ8A*], *COQ8B*, and *COQ9*) followed. Five clinical syndromes are attributed to CoQ_{10} deficiency, and they are considered in the following section.

FIGURE 144.2 Morbidity map of human mitochondrial DNA. Disorders caused by mutations in protein-coding genes are shown in *red*. Disorders caused by mutations in gene controlling protein synthesis are shown in *blue*. Abbreviations: CO, cytochrome oxidase; cyt *b*, cytochrome *b*; FBSN, familial bilateral striatal necrosis; LHON, Leber hereditary optic neuropathy; LS, Leigh syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonus epilepsy with ragged red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; ND, NADH dehydrogenase; PEO, progressive external ophthalmoplegia.

Defects of Mitochondrial Ribonucleic Acid (mtRNA) Translation

The mitochondrial genome is transcribed into 13 mRNAs, which are translated by mitoribosomes into the 13 mtDNA-encoded OxPhos subunits. As described in a comprehensive review, this process can be divided into two phases: a posttranscriptional phase (involving tRNA modifications, aminoacyl-tRNA synthetases, and processing of ribosomal proteins) and mtRNA translation (initiation, elongation, termination, and recycling). Representative examples of defects of each step of the mitochondrial translation process are briefly highlighted.

Abnormal Transfer RNA Modifications

Pseudouridylation modification is thought to promote stability and conformation of mitochondrial and nuclear tRNAs. Mutations in pseudouridine synthase 1 (*PUS1*) differentially impair nuclear and mitochondrial tRNA maturation causing mitochondrial myopathy, lactic acidosis, and sideroblastic anemia; in addition, psychiatric symptoms and facial dysmorphism are likely due to abnormal cytosolic protein synthesis.

The conundrum of spontaneous improvement in *infantile reversible COX-deficient myopathy* (more accurately designated reversible infantile respiratory chain deficiency [RIRCD]) was

resolved by elucidation of the tRNA modification processes in this disorder. RIRCD is due to homoplasmic mutations in *MT-TE*, which encodes mt-tRNA^{Glu}. Pathogenesis of the disease became more complex when patients in two families were found to harbor mutations in the *TRMU* gene, which modifies a wobble uridine base in mt-tRNA^{Glu}. Skeletal muscle from infants in the initial symptomatic phase showed significantly decreased 2-thiouridylation due to defective TRMU activity, which exacerbated the effect of the mtRNA^{Glu} mutation and triggered the mitochondrial translation defect, thus demonstrating an nDNA-modifying effect on the mtDNA mutation.

Mutations in 17 highly specialized aminoacyl-tRNA synthetases (ARs), which covalently link an amino acid to its cognate tRNA (tRNA charging), are associated with multiple specific clinical syndromes. Mitoribosomes consist of two mRNA components (12S and 16S rRNAS) and of novel about 30 and 50 nDNA-encoded proteins. Of the roughly 80 ribosomal proteins, 6 have been firmly linked to mitochondrial diseases: MRPL3, MRPS16, MRPS22, MRPL44, MRPL12, and MRPS34. Patients with defects of mitochondrial elongation factor genes (*GFM1* encoding EFG1; *TUFM*, EF-Tu$_{mt}$; and *TSFM*, EF-TS$_{mt}$) typically present with infantile-onset multisystemic diseases. Of the three known mitochondrial translation termination factors, which catalyze release of fully synthesized polypeptides, mutations have only been identified in a poorly characterized ribosome-recycling factor encoded by *C12orf65* in two unrelated families with LS, optic atrophy, and ophthalmoplegia. Mutations in two mitochondrial translation activators, both required for COX, have been linked to human diseases. Mutations in the gene *TACO1* (encoding translational activator for COX I), cause late-onset LS and COX deficiency, whereas mutations in *LRPPRC* (which encodes a leucine-rich pentatricopeptide repeat–containing protein) have been identified as the cause of a distinctive LS prevalent in French Canadians. Mutations of *RMND1* cause mitochondrial translational defects affecting multiple organs; however, the function of the encoded protein, which contains a domain of unknown function (DUF 155), remains a mystery.

Defects of the Inner Mitochondrial Membrane Lipid Milieu

The respiratory chain resides in the phospholipid component of the IMM and alterations in the lipid milieu are increasingly associated with mitochondrial encephalomyopathy. Cardiolipin, a dimeric molecule composed of two phosphatidylglycerol moieties connected by a glycerol group, is the signature mitochondrial phospholipid and a major component of the IMM, where it is synthesized. Cardiolipin deficiency was first documented—together with mutations in the gene encoding tafazzin (*TAZ*)—in patients with Barth syndrome, an X-linked mitochondrial myopathy and cardiomyopathy, with neutropenia and stunted growth.

Similar to Barth syndrome, Sengers syndrome affects primarily heart and muscle, with the distinctive additional clinical feature of congenital cataracts. Whole exome sequencing revealed mutations in the acylglycerol kinase (*AGK*) gene. Notably, lack of phosphatidic acid is a precursor of cardiolipin, thus providing a point of convergence in Sengers syndrome and Barth syndrome, which could account for the clinical similarities between the two disorders.

The mitochondrial-associated endoplasmic reticulum (ER) membrane (MAM) is the close physical and functional association between ER and mitochondria. MAMs are involved in multiple functions, including lipid transport, cholesterol metabolism, calcium signaling, energy metabolism, apoptosis, and mitochondrial dynamics.

New diseases have been associated with MAM dysfunction, including the 3-methylglutaconic aciduria (MEG), Deafness (D), Encephalopathy (E), and Leigh-like disease (L) (MEGDEL) syndrome, in which the SERAC protein is located in the MAM and controls exchange of phospholipids between the ER and mitochondria. Interestingly, a central role of MAM in the pathogenesis of Alzheimer disease has been well documented.

Defects of Mitochondrial Dynamics

Mitochondria are highly dynamic organelles that move around the cell on microtubular tracks and, similar to their bacterial precursors, they fuse and divide, thus forming tubular networks that favor a balanced distribution of energy throughout the cell. Impairment of mitochondrial motility, fusion, or fission causes the nervous system particularly susceptible, as it is highly dependent on oxidative energy, and mitochondria must travel long distances along central axons and peripheral nerves.

Mitochondrial fusion requires coordinated action of multiple guanosine triphosphatases (GTPases) in the outer mitochondrial membrane (OMM), namely mitofusins MFN1 and MFN2, and in the IMM, namely OPA1.

Mitochondrial fission requires cytosolic dynamin-related protein 1 (DRP1; also a guanosine triphosphatase), which is recruited to the OMM together with two partners, mitochondrial fission (FIS1) and mitochondrial fission factor (MFF). Once recruited to the OMM, DRP1 forms a spiral that wraps around the mitochondrion like a noose and severs the mitochondrial membrane using guanosine triphosphate hydrolysis.

Defects of Mitochondrial DNA Maintenance

These disorders have been traditionally subdivided into two groups (1) mtDNA depletion syndromes (MDS) manifesting early in life and presenting as myopathy, hepatocerebral disease, or encephalomyopathy and (2) multiple mtDNA deletions, usually associated with chronic progressive external ophthalmoplegia (CPEO) with other manifestations that are predominantly neurologic (PEO-plus).

The disorders of mtDNA maintenance are usually caused either by defects of mtDNA replication that are catalyzed by polymerase (POLG; genes *POLG* and *POLG2*) and by the helicase Twinkle (*PEO1*) or by altered homeostasis of the intramitochondrial deoxynucleoside triphosphates pool that is controlled by multiple genes including *TK2* (encoding thymidine kinase 2), *DGUOK* (encoding deoxyguanosine kinase), and *TYMP* (encoding thymidine phosphorylase). In addition, the gene encoding adenine nucleotide translocase 1 (*ANT1*) causes autosomal dominant PEO. Another mutant gene (*OPA1*), which is required mitochondrial fusion, has curiously been associated with autosomal dominant PEO-plus.

It has become increasingly evident that both mtDNA depletion and multiple mtDNA deletions often coexist in the same patient and are often caused by the same genes that cause either isolated depletion or multiple deletions of mtDNA (Table 144.2). A peculiarity of these disorders is that—although they are unequivocally mendelian—they share many features of mitochondrial genetics, including heteroplasmy and the threshold effect.

TABLE 144.2 Paradigms of Mitochondrial DNA-Mutation Disorders[a]

		mtDNA Single Deletions		tRNA		ATPase6	
Tissue	Symptom/Sign	KSS	Pearson	MERRF	MELAS	NARP	MILS
CNS	Seizures	−	−	+	+	−	+
	Ataxia	+	−	+	+	+	±
	Myoclonus	−	−	+	±	−	−

	Intestinal pseudo-obstruction	−	−	−	−	−	−

Abbreviations: −, absent; +, present; ±, variably present; CNS, central nervous system; GI, gastrointestinal; KSS, Kearns-Sayre syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonus epilepsy with ragged red fibers; MILS, maternally inherited Leigh syndrome; mtDNA, mitochondrial DNA; NARP, neuropathy, ataxia, and retinitis pigmentosa; PNS, peripheral nervous system; tRNA, transfer RNA.
[a]Typical features are highlighted in red for each disorder except MILS, which is diagnosed neuropathologically.

Disorders of Mitochondrial Protein Importation

A prerequisite for the assembly of any OxPhos complex is the import of nDNA-encoded subunits from the cytoplasm into mitochondria, thus adding one more category to the indirect hits, namely defects in the mitochondrial importation machinery.

DIAGNOSIS

Mitochondrial DNA-Related Diseases

Mitochondria and mtDNA are ubiquitous, which explains why every tissue in the body can be affected by mtDNA mutations. This is illustrated in Figure 144.2 depicting mtDNA as a veritable Pandora box (abbreviated morbidity map). Table 144.2 is a compilation of symptoms and signs reported in patients with three different types of mtDNA mutations, including single deletions, point mutations in two distinct tRNA genes, and point mutations in a protein-coding gene. As shown by the boxes, certain constellations of symptoms and signs are sufficiently characteristic to make the diagnosis relatively easy in typical patients. On the other hand, because of the peculiar rules of mitochondrial genetics, different tissues harboring the same mtDNA mutation may be affected to different degrees or not at all, which explains the sometimes puzzling variety of syndromes associated with carriers of mtDNA mutations, even within a single pedigree.

Among the maternally inherited encephalomyopathies, four syndromes are more frequent. The first is MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), which usually presents in children or young adults after normal early development. Symptoms include seizures, migraine-like headache, and stroke-like episodes causing cortical blindness, hemiparesis, or hemianopia. Magnetic resonance imaging (MRI) of the brain shows "infarcts" that do not correspond to the distribution of major vessels, raising the question of whether the strokes are vascular due to mitochondrial microangiopathy (Fig. 144.3). The most common cause of MELAS is *m3243A>G* in the *tRNA*Leu(UUR) gene, but more than 20 other mutations have been associated with this disorder.

The second syndrome is *MERRF* (myoclonus *epilepsy with ragged red fibers*), characterized by myoclonus, seizures, myopathy, and cerebellar ataxia. Less common signs include dementia, hearing loss, peripheral neuropathy, and multiple lipomas. The typical mtDNA mutation in MERRF is the m.8344A>G in the *tRNA*Lys gene, but other mutations in the same gene have been reported.

FIGURE 144.3 Characteristic brain magnetic resonance imaging abnormalities in mitochondrial encephalomyopathies. These T2-weighted images show bilateral putaminal hyperintensities in a child with cytochrome c oxidase–associated Leigh syndrome **(top left panel)**, bilateral globus pallidus hyperintensities in a child with a familial Leigh syndrome phenotype **(top right)**, a left posterior cerebral hyperintense stroke-like lesion in a child with mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) **(bottom left)**, and bilateral white matter hyperintensities in a child with Kearns-Sayre syndrome (KSS) **(bottom right)**.

The third syndrome has two clinical presentations. The first is NARP (neuropathy, ataxia, and retinitis pigmentosa), which usually affects young adults and causes retinitis pigmentosa, dementia, seizures, ataxia, proximal weakness, and sensory neuropathy. The second is maternally inherited LS (*MILS*), a more severe infantile encephalopathy with characteristic symmetric lesions in the basal ganglia and the brainstem (see Fig. 144.3). As noted by the late Anita Harding in her original description of this syndrome, the two major causative mutations (m.8993G>T or m.8993C>T, both affecting the same gene *MTATP6*) affect maternal relatives in the same family with those afflicted with MILS having higher mutation loads than individuals with NARP.

The fourth syndrome, LHON, is characterized by acute or subacute loss of vision in young adults, more frequently males, due to bilateral optic atrophy. Mutations in three genes of complex I (ND genes) account for more than 90% of LHON, *m.11778G>A* in *ND4*, *m.3460G>A* in *ND1*, and *m.14484T>C* in *ND6*. Epidemiologic studies have shown that LHON is the most common mtDNA-related disorder in adults. Epigenetic factors contribute to disease expression in homoplasmic patients by virtue of increased penetrance due to the European mtDNA haplogroup J and a protective effect of estrogens in women who are less frequently affected than men.

Three sporadic conditions are associated with mtDNA single deletions, Kearns-Sayre syndrome (KSS), CPEO, and *Pearson syndrome*. All three conditions are typically sporadic; however, a few cases of maternal transmission have been reported. A multicenter retrospective study of 226 families has confirmed that women carrying single mtDNA deletions have a low risk of having affected children (1 in 24).

KSS is a multisystem disorder with the obligate triad of impaired eye movements (PEO and ptosis), pigmentary retinopathy and heart block (often requiring installment of an automatic implantable cardioverter defibrillator-pacemaker), plus ataxia, or markedly elevated cerebrospinal fluid (CSF) protein (>100 mg/dL). Frequent additional signs include dementia, endocrinopathies (diabetes mellitus, growth hormone deficiency, and hypoparathyroidism), and lactic acidosis.

CPEO is a relatively benign disorder characterized by ptosis, PEO, and proximal myopathy. In addition, patients often develop dysphagia.

Pearson syndrome, characterized by sideroblastic anemia and exocrine pancreatic dysfunction, is usually a fatal disorder of infancy. Due to *mitotic segregation* of deleted mtDNAs resulting in loss of the mutant mtDNA from blood cells but increased mutation burden in muscle and other postmitotic cells, the phenotype often evolves into CPEO or KSS in some surviving babies.

It is often stated that any patient having multiple organ involvement and evidence of maternal inheritance should be suspected of harboring a pathogenic mtDNA point mutation until proven otherwise. Although this "rule of thumb" has some practical value, it is also important to keep in mind that patients with involvement of a single tissue can still have pathogenic point mutations of mtDNA. This is especially true for skeletal muscle. As described earlier, isolated myopathy with PEO can be due to single large-scale mtDNA deletions, but isolated myopathy without PEO has been associated with point mutations in several tRNA genes, which can be due to generalized but skewed heteroplasmy in muscle. However, a simple nonmaternal inherited rule can be applied to pure mitochondrial myopathies due to somatic mutations in protein-coding mtDNA genes, including subunits of complex I, complex III (including cytochrome *b*, *MTCYB*), or complex IV, accompanied by severe exercise intolerance, myalgia, and myoglobinuria.

Mendelian Inheritance

LS is the most frequent mitochondrial disorder affecting infants and children and reflecting the ravages of energy shortage on the developing nervous system; LS is a defined neuropathologically or neuroradiologically entity by bilateral symmetric lesions all along the neuraxis but especially in the basal ganglia, thalami, brainstem, and cerebellar roof nuclei. Microscopically, there is neuronal loss, proportionate loss of myelin, reactive astrocytosis, and proliferation of cerebral microvessels. Clinically, these children manifest psychomotor retardation or regression, respiratory abnormalities, hypotonia, failure to thrive, seizures, and optic atrophy. Although we have highlighted mtDNA mutations in complex V genes causing LS (NARP/MILS), several other defects in mtDNA-encoded complex I (NADH dehydrogenase [ND]) genes as well as mutations in nuclear encoded subunits of complexes I, II, and IV frequently cause LS.

Besides LS, four distinct presentations have been attributed to direct hits in complex I deficiency: fatal infantile lactic acidosis, neonatal cardiomyopathy with lactic acidosis, leukodystrophy with macrocephaly, and hepatopathy with renal tubulopathy. Likely, these disorders represent variations of the common LS theme rather than separate clinical entities: Usually, these children appear healthy at birth or early in life, but disease progression is rapid and relentless, leading to death often before 1 year of age.

It has long been known that complex IV deficiency is a common cause of LS, but years went by before a mutated gene (*SURF1*) was associated with LS, the first example of an "indirect hit." Mutations in the COX assembly gene *SCO2* cause a severe combination of neonatal cardiomyopathy with encephalopathy, which is fatal in the first weeks or months of life. Importantly, SCO2 mutations can simulate spinal muscular atrophy (SMA); therefore, it is important to consider *SCO2* mutations in patients with the clinical picture of SMA but without mutations in the SMN gene and with cardiomyopathy and COX-deficiency in muscle histology. Mutations in several other genes encoding COX assembly proteins have been associated with encephalopathy resembling LS together with involvement of other tissues. However, mutations in *SCO1* cause encephalohepatopathy, mutations in *COX10* cause encephalonephropathy, and mutations in *COX15* cause encephalocardiopathy as do mutations in *C2orf64*. Additional disorders due to indirect hits and resulting in generalized COX deficiency, including an unusual "toxic" mechanism of COX inhibition, have been reported. Indirect hits in complex V are rather frequently associated with mutations in the gene *TMEM70*, resulting in defective assembly of ATP synthase. Most patients harboring *TMEM70* mutations were severely affected with neonatal hypotonia, apneic spells, psychomotor delay, hypertrophic cardiomyopathy, and profound lactic acidosis, whereas a minority presented with additional infantile-onset cataracts, early-onset gastrointestinal dysfunction, and multiple joint contractures.

Indirect hits include heterogeneous diseases with five major phenotypes due to CoQ_{10} deficiency (Fig. 144.4). These disorders are important to diagnose because they often respond to CoQ_{10} supplementation. The first patients reported in 1989 were a pair of sisters, ages 12 and 14 years old with a mitochondrial disorder characterized by encephalopathy (mental retardation, seizures, and mild ataxia) and myopathy with recurrent myoglobinuria. The triad of mitochondrial myopathy, myoglobinuria, and encephalopathy has been reported in a few other patients. The second syndrome is childhood-onset cerebellar atrophy and ataxia, with variable additional symptoms, including neuropathy, seizures, mental retardation, and muscle weakness. The molecular basis of this phenotype was identified in some but not all patients, and the mutated gene was *ADCK3/COQ8A*. The third syndrome was an infantile multisystemic disease, which typically manifests as encephalopathy and nephropathy (particularly steroid-resistant nephrotic syndrome). This syndrome was initially associated with mutations in COQ2 and PDSS and subsequently in additional genes required for CoQ_{10} biosynthesis including *PDSS1*, *PDSS2*, *COQ4*, and *COQ9*. The fourth syndrome, dominated by severe nephropathy and typically leading to end-stage renal disease, was originally attributed to *COQ2* gene mutations, whereas steroid-resistant nephrosis and end-stage renal failure associated with sensorineural deafness was linked to *COQ6* mutations. The fifth syndrome is isolated myopathy and, in a few cases, has been due to multiple acyl-coenzyme A (CoA) dehydrogenases deficiency causing secondary CoQ_{10} deficiency.

Defects of the Inner Mitochondrial Membrane Lipid Milieu

Phospholipid metabolism and the lipid composition of the IMM were relatively neglected in the study of mitochondrial diseases, but there was a recent awakening of this subject and several new disorders were discovered, thanks in part to whole exome sequencing.

Barth syndrome is an X-linked disorder characterized by mitochondrial cardiac and skeletal myopathy, cyclic neutropenia,

FIGURE 144.4 Schematic representation of the clinical spectrum associated with primary coenzyme Q_{10} deficiencies. Hypertrophic cardiomyopathy (HCM), steroid-resistant nephrotic syndrome (SRNS), multiple system atrophy (MSA), and cerebellar hypoplasia (cerebellar hypo).

and growth retardation and, as previously noted, is due to *TAZ* mutations that alter cardiolipin, the most abundant phospholipid component of the IMM.

Sengers syndrome, an autosomal recessive disorder, was described in 1975 and consisted of congenital cataracts, hypertrophic cardiomyopathy, skeletal myopathy, exercise intolerance, and lactic acidosis. This syndrome was ultimately attributed through exome sequencing to mutations in the gene (*AGK*) encoding acylglycerol kinase.

A third disorder of the mitochondrial lipid milieu was identified in 15 patients with a *congenital myopathy* characterized by early-onset muscle weakness and mental retardation with protracted course (most patients were alive at the time of publication and only four had died between the ages of 2½ and 28 y). The hallmark of the disease was the presence in muscle of greatly enlarged mitochondria (megaconial disease) displaced at the periphery of the fibers and the genetic cause was due to mutations in the gene (*CHKB*) encoding choline kinase beta.

A genetic alteration of phospholipid metabolism explained a syndrome characterized by 3-methylglutaconic aciduria (3-methylglutaconic aciduria type IV, deafness, and encephalopathy, Leigh-like which was dubbed *MEGDEL*). This syndrome was caused by mutations in the phospholipid remodeling gene *SERAC1*, a key player in intracellular cholesterol trafficking and a member of the MAMs.

Defects of Mitochondrial Translation

Mitochondrial translation is a complex mechanism that requires the cooperation of almost 100 different proteins needed to form the mitoribosome, elongation factors, and aminoacyl-tRNA synthases. It is not surprising that mitochondrial translational defects typically present with diverse clinical phenotypes, often infantile onset and severe manifestations with multisystemic disease and LS being the most prevalent. However, a few distinct phenotypes have emerged in this group of heterogeneous disorders. As previously noted, mitochondrial myopathy, lactic acidosis, and sideroblastic anemia can be caused not only by *PUS1* mutations but also by *YARS* mutations. RIRCD to a homoplasmic $tRNA^{Glu}$ is particularly important to diagnose because, with proper supportive care, children typically improve spontaneously and eventually become clinically normal. Pathogenic mutations in the gene *DARS* (encoding aspartyl-tRNA synthethase) cause brainstem and spinal cord involvement and lactate elevation (*LBSL*) in affected children with cerebellar ataxia, spasticity, dorsal column dysfunction, and mild cognitive decline. Equally severe mutations in the gene *RARS2* (encoding arginyl-tRNA synthetase) have been identified in three patients with severe infantile encephalopathy with *pontocerebellar hypoplasia*. Mutations in *EARS2*, encoding glutamyl-tRNA synthetase, were identified by whole exome sequencing in a cohort of 11 unrelated cases with symmetric cerebral white matter abnormalities and signal abnormalities of the thalami, midbrain, pons, medulla oblongata, and cerebellar white matter. All patients share an infantile-onset and rapidly progressive disease with severe lactic acidosis. Mutations in *MARS2*, encoding the methionyl-tRNA synthetase, were found to be responsible for *autosomal recessive spastic ataxia with leukoencephalopathy*.

Defects of mitoribosomes have been associated with complex multisystemic disorders sometimes presenting with congenital abnormalities (dysmorphism and heart defects); however, in one family with *MPRL3* mutations, four siblings manifested fatal infantile-onset hypertrophic cardiomyopathy and psychomotor retardation. Similarly, patients with abnormal mitochondrial translational elongation factors typically present with fatal infantile diseases with early hepatoencephalopathy with *GFM1* (EFG1) mutations and macrocystic leukodystrophy and micropolygyria due to *TUFM* (EF-Tu_{mt}) defects.

Defects of Mitochondrial Dynamics

There is a group of disorders due to numerous mutations in mitochondrial fusion proteins and, less commonly, in fission proteins. Mutations in fusion proteins, such as OPA1, result in a dominant optic atrophy (DOA or Kjer disease), the nDNA blindness corresponding to the mtDNA disorder LHON. Other mutations in fusion proteins, such as MFN2 or GADP1, result in Charcot-Marie-Tooth neuropathies (types 2A and 4A).

Two infants with distinct mutations in fission genes (*DRP1* and *MFF*) showed both mitochondrial and peroxisomal abnormalities, and they were severely affected with rapidly fatal encephalopathy and lactic acidosis.

Defects of Mitochondrial DNA Maintenance

Here, we consider the main clinical phenotypes associated with MDS, with multiple mtDNA syndromes (PEO-plus), and, finally, with combined appearance of mtDNA depletion and of multiple mtDNA deletions.

Mitochondrial DNA Depletion Syndromes

Myopathic Mitochondrial DNA Depletion Syndromes

Patients usually present in the first year of life with failure to thrive, hypotonia, weakness, and sometimes PEO. They usually die in childhood from pulmonary insufficiency but severity of weakness and survival vary considerably. The myopathic MDS is most commonly due to mutations in the gene (*TK2*) encoding mitochondrial thymidine kinase 2. More than 90 patients have been reported in the literature with a range of more than 45 different mutations. Notably, mutations in *TK2* can also cause a phenocopy of SMA; therefore, it is of practical importance to screen for *TK2* mutations in patients with SMA but without mutations in the *SMN1* gene.

Encephalomyopathic Mitochondrial DNA Depletion Syndromes

Two variants of this condition are both due to a defect of succinyl-CoA lyase activity in the Krebs cycle. Mutations in the gene (*SUCLA2*) encoding the ATP-dependent succinyl-CoA lyase SUCLA2 cause severe psychomotor retardation, muscle hypotonia, hearing loss, generalized seizures, knee and hip contractures, mild ptosis, lactic acidosis, and methylmalonic aciduria. There is only moderate mtDNA depletion (about 30%) in muscle, whereas MRI of the brain is suggestive of LS. Mutations in the gene (*SUCLG1*) encoding the guanosine triphosphate-dependent isoform SUCLG1 cause a much more severe and rapidly fatal phenotype with mtDNA depletion in both muscle and liver, characterized clinically by dysmorphic features, congenital lactic acidosis, and methylmalonic aciduria. A less dismal course, more like the SUCLA2 phenotype, is correlated to the degree of residual activity.

Patients with mtDNA depletion are due to mutations in RRM2B (encoding the small subunit, p53R2, of the p53-inducible ribonucleotide reductase protein). Infants are hypotonic and children are weak but may also manifest nephropathy and central

nervous system involvement with microcephaly, seizures, and developmental delay.

Hepatocerebral Mitochondrial DNA Depletion Syndromes

Mutations in three other genes, *DGUOK*, *MPV17*, and *POLG*, also cause liver and brain involvement. Mutations in *DGUOK*, encoding the mitochondrial deoxyguanosine kinase, were first reported in 2001. Severe mutations cause fatal infantile hepatopathy and brain involvement, whereas milder mutations cause isolated liver disease and are compatible with longer survival.

Mutations in *MPV17*, which encodes a small mitochondrial membrane protein of unknown function, cause a rather typical hepatocerebral syndrome in Caucasian children but is associated with a peculiar neurohepatopathy that is prevalent in the Navajo population due to a founder *MPV17* mutation. The clinical features of Navajo neurohepatopathy (NNH) include peripheral and central nervous system involvement, acral mutilation, corneal scarring or ulceration, liver failure, and immunologic derangement.

Alpers-Huttenlocher syndrome is the most important form of hepatocerebral MDS, and it has been attributed to mutations in *POLG*. Alpers-Huttenlocher syndrome is defined as a disorder of childhood by the tetrad of refractory seizures, episodic psychomotor regression, cortical blindness, and hepatopathy with micronodular cirrhosis. It is crucially important not to expose these children to valproate, which often precipitates fulminant hepatic failure.

Syndromes due to Multiple Mitochondrial DNA Deletions

Mutations in ANT1

Mutations in the gene for one isoform of the adenine nucleotide translocator (*ANT1*) have been identified in patients with autosomal dominant PEO, sometime associated with psychiatric disorders. In a seminal paper, multiple mtDNA deletions were most abundant in brain, followed by cardiac and skeletal muscle. Sporadic PEO may also infrequently be due to mutations in *ANT1* and the association of mitochondrial myopathy and cardiomyopathy, even in patients with recessive inheritance and without PEO, should raise the question of *ANT1* mutations.

Mutations in PEO1

In 2001, autosomal dominant PEO with multiple mtDNA deletions was associated with mutations in the gene (*PEO1*), encoding a mitochondrial helicase called *Twinkle*, an essential factor for mtDNA maintenance and for the regulation of mtDNA copy number. A review of 33 patients from 26 families showed that the most common symptoms were ptosis (97%) and ophthalmoparesis (94%), followed by exercise intolerance (52%) and mild proximal weakness (33%). Central nervous system involvement was infrequent and included visual impairment, migraine, lethargy, hearing loss, and epilepsy. Cardiac problems were noted in 24% of the patients. A relatively benign long-term progression was noted in a large family with autosomal dominant isolated PEO.

Mutations in POLG

Mutations in the gene encoding the only mitochondrial polymerase, *POLG*, have emerged as major causes of a vast array of mitochondrial disorders. More than 150 mutations have been described in all three domains of the gene, exonuclease, linker, and polymerase and may cause either autosomal dominant or autosomal recessive PEO, a syndrome comprising autosomal recessive sensory ataxic neuropathy, dysarthria, and ophthalmoparesis; mitochondrial recessive ataxia syndrome; or parkinsonism with or without PEO.

Mutations in OPA1

One unexpected gene was recently added to those described earlier and associated with myopathy and PEO, *OPA1*. This was unexpected because mutations in *OPA1* had been initially associated with a purely ophthalmologic condition, DOA or Kjer disease, and because the gene product is a mechanoenzyme associated with mitochondrial fusion rather than with mitochondrial maintenance.

However, a syndromic disorder, often dubbed DOA-plus, has emerged, which is characterized more or less sequentially by optic atrophy with visual failure, sensorineural deafness, ataxia, myopathy, axonal sensory motor polyneuropathy, and PEO. Muscle biopsy in these patients shows scattered ragged blue, COX-negative fibers and multiple mtDNA deletions. The relationship between this defect of mitochondrial dynamics and altered mitochondrial maintenance is intriguing. Two explanations have been proposed: decreased ability by the organelles to repair stress-induced mtDNA damage or accelerated accumulation of preexisting age-associated somatic mtDNA mutations.

Coexistence of Mitochondrial DNA Depletion and Mitochondrial DNA Multiple Deletions

Mitochondrial Neurogastrointestinal Encephalomyopathy

One of the disorders in which the coexistence of multiple mtDNA deletions and mtDNA depletion was first recognized is mitochondrial neurogastrointestinal encephalomyopathy (MNGIE). This autosomal recessive multisystemic syndrome is characterized by mitochondrial myopathy with ptosis and PEO, peripheral neuropathy, gastrointestinal dysmotility causing severe cachexia, and leukoencephalopathy without cognitive impairment. MNGIE is due to mutations in the gene (*TYMP*) encoding thymidine phosphorylase, resulting in elevated levels of thymidine and deoxyuridine in plasma and tissues. The disease usually starts in the late teens and is relentlessly progressive, with an average age of death at 37 years. Molecular analysis has shown over 50 *TYMP* mutations resulting in mtDNA multiple deletions, depletion, and site-specific somatic mtDNA point mutations in multiple tissues. A mouse model has demonstrated that increased levels of thymidine and deoxyuridine imbalance mitochondrial deoxynucleotide triphosphate pools, resulting in mtDNA instability.

Infantile-onset spinocerebellar ataxia was described in the 1970s in Finland. Between 9 and 18 months, children develop acute or subacute ataxia, hypotonia, athetosis, and areflexia, and by teenage years, they lose independent ambulation. Additional symptoms include PEO, optic atrophy, sensorineural hearing loss, cognitive impairment, sensory neuropathy, and autonomic nervous system dysfunction. In 2005, this autosomal recessive disorder was attributed to mutations in *PEO1*. Both brain and liver showed mtDNA depletion.

In addition to causing early childhood-onset myopathic mtDNA depletion, mutations in *TK2* can also cause adult-onset myopathy with mtDNA depletion and even late-onset PEO with multiple mtDNA deletions rather than mtDNA depletion.

Mutations in *RRM2B* can also be associated with autosomal dominant or recessive PEO and multiple mtDNA deletions.

Exome sequencing revealed *DGUOK* mutations in five adult patients with PEO and mitochondrial myopathy with multiple mtDNA deletions: Only one of these patients had had liver problems in childhood. Mutations in *MPV17*, in addition to causing juvenile-onset mtDNA depletion, can also cause adult-onset PEO-plus with multiple mtDNA deletions in muscle.

DIAGNOSTIC WORKUP

Laboratory

Lactic acidosis is a common finding in OxPhos disorders, and the lactate-to-pyruvate ratio is often elevated (>20:1). Information about CSF lactate and pyruvate is important because CSF values can be increased in children with encephalopathy and normal blood lactate. However, lack of lactic acidosis does not exclude the diagnosis. For example, in patients with NARP or MILS, blood lactate and pyruvate can be normal or only mildly elevated. Serum creatine kinase levels are usually normal or modestly increased except, of course, in patients with myopathy during episodes of myoglobinuria. As another exception to this rule, and a useful diagnostic clue, serum creatine kinase values can be markedly elevated in children with the myopathic form of mtDNA depletion, such as those with mutations in the gene (*TK2*) encoding mitochondrial thymidine kinase. Another important laboratory test is plasma thymidine, which is greatly increased in patients with MNGIE, an autosomal recessive disease due to mutations in *TYMP* encoding thymidine phosphorylase.

Neuroradiology

Bilateral MRI T2 signal hyperintensities in basal ganglia and brainstem are indicative of LS. Stroke-like lesions predominantly affecting the cortex, often in the posterior cerebral hemispheres, are typically seen in patients with MELAS. Increased MRI T2 signal abnormality of the central white matter is sometimes observed in KSS, whereas basal ganglia calcifications are common in both MELAS and KSS syndrome (see **Fig. 144.3**). White matter signal abnormalities are distinctively seen in patients with complex I deficiency or in children with mtDNA translation defects or in several patients with problems of mtDNA maintenance. Proton magnetic resonance spectroscopy reveals lactate accumulation in the CSF and in specific areas of the brain, where lactate concentration can be compared to the concentration of *N*-acetylaspartate, an indicator of cell viability.

Exercise Physiology

Impaired oxygen extraction by exercising muscle can be detected by near-infrared spectroscopy, which measures the degree of deoxygenation of hemoglobin. A simpler test is based on the measurement of the P_{O_2} in cubital venous blood after forearm aerobic exercise. P_{O_2} rises paradoxically in patients with mitochondrial myopathy or PEO, and the degree of rise reflects the severity of oxidative impairment. By phosphorus 31 magnetic resonance spectroscopy, the ratio of phosphocreatine to inorganic phosphate can be measured in muscle at rest, during exercise, and during recovery. In patients with mitochondrial dysfunction, phosphocreatine to inorganic phosphate ratios are lower than normal at rest, decrease excessively during exercise, and return to baseline more slowly than normal.

PATHOLOGY

Skeletal Muscle

Muscle biopsy has a central role in the diagnosis of primary mtDNA-related disorders but is equally important in diagnosing patients with defects of mtDNA maintenance, who have strictly mendelian inheritance and secondary mtDNA alterations. In both types of disorders, abnormal mitochondrial proliferation, a hallmark of mitochondrial dysfunction, can be revealed with the modified Gomori trichrome stain (RRF) or better with the SDH reaction (ragged blue fibers) (**Fig. 144.5**). RRF are present in muscle biopsies from patients with most disorders due to mtDNA mutations although rare exceptions include NARP/MILS and LHON. Most cases of mendelian inheritance rarely are diagnosable by the presence of RRF or ragged blue fibers, but these types of fibers are exceptionally detectable in patients with either mtDNA depletion or mtDNA multiple deletions.

The COX histochemical reaction typically reveals scattered COX-negative and COX-deficient fibers, which usually correspond to—but are not confined to—RRF. RRF are COX-positive in two main conditions: (1) typical MELAS syndrome and (2) mutations in mtDNA genes encoding cytochrome *b* or complex I subunits. To confirm the pathogenicity of an mtDNA mutation, single fibers can be dissected out of thick cross-sections of muscle and used to determine the levels of a given mutation by polymerase chain reaction. Finding higher levels of the

FIGURE 144.5 Serial sections from the muscle biopsy of a patient with myoclonus epilepsy with ragged red fibers syndrome. With the modified Gomori trichrome stain **(A)**, two ragged red fibers are evident. The same fibers appear *ragged-blue* with the succinate dehydrogenase (SDH) stain **(B)**, are pale with the cytochrome *c* oxidase (COX) stain **(C)**, and appear more or less intensely blue with the combined COX/SDH stain **(D)**. In contrast to the checkerboard appearance of the muscle biopsy in an mitochondrial DNA-related disease, the biopsy from a patient with mutations in *SCO2*, an nDNA assembly gene of COX, shows normal fiber type–related variability in SDH staining intensity **(E)** but uniform lack of COX activity **(F)**.

mutation in affected (ragged red or COX-negative fibers) than in unaffected (non–ragged red, COX-positive fibers) is strong evidence that the mutation in question is pathogenic.

Electron microscopy has lost much of its historical diagnostic value, but it can reveal focal accumulations of mitochondria or mitochondria with paracrystalline inclusions in cases in which histochemical results are equivocal.

Neuropathology

The major neuropathologic findings in mitochondrial encephalomyopathies consist of four histologic lesions: spongy degeneration, neuronal loss, gliosis, and demyelination. Although these lesions are nonspecific, their distribution patterns vary in patients with different mtDNA-related disorders. Thus, the neuropathology of KSS is characterized by spongiform degeneration, which is usually generalized and affects both gray and white matter. In MELAS, multifocal necrosis predominates, affecting not only the cerebral cortex or the subcortical white matter but also the cerebellum, thalamus, and basal ganglia. Calcification of basal ganglia is also common. In MERRF, neuronal degeneration, astrocytosis, and demyelination affect preferentially the cerebellum (especially the dentate nucleus), the brainstem (especially the olivary nucleus), and the spinal cord. In LS, due to either mtDNA-related diseases or mendelian conditions, there are symmetric, bilateral foci of necrosis in the basal ganglia, thalamus, midbrain, and pons. Microscopically, the lesions show vascular proliferation, gliosis, neuronal loss, demyelination, and cystic cavitation.

BIOCHEMICAL FINDINGS

All 37 mtDNA-encoded genes are required for synthesis of the mitochondrial OxPhos pathway (see **Fig. 144.1**); therefore, disorders due to mutations of mtDNA are usually associated with biochemical defects of OxPhos. Skeletal muscle is the preferred tissue for biochemical analysis because it is rich in mitochondria, it is invariably affected in multisystem disorders (mitochondrial encephalomyopathies), and it is the most common tissue affected in isolation (mitochondrial myopathies). Because mitochondrial proliferation in muscle (RRF) is a common occurrence, activities of respiratory chain complexes should be referred to the activity of citrate synthase, a nuclear-encoded enzyme of the mitochondrial matrix that is a good marker of mitochondrial abundance.

Biochemical studies in muscle extract from patients with mtDNA-related disorders yield two main types of results. The first pattern consists of partial defects in the activities of multiple complexes containing mtDNA-encoded subunits (I, III, and IV) contrasting with normal or increased activities of SDH (complex II) and citrate synthase. The second pattern is a severe deficiency in the activity of one specific respiratory complex. As a rule, the first pattern is found in patients with single mtDNA deletions (eg, KSS) or mutations in tRNA genes (eg, MELAS, MERRF) because these genetic errors impair mitochondrial protein synthesis in toto. The second pattern is typical of mutations in mtDNA protein-coding genes. For example, mutations in the cytochrome *b* gene cause isolated complex III deficiency. However, mutations in ND genes, which are encountered with increasing frequency in patients with MELAS, LS, LHON, or overlap syndromes, cause inconsistent and often modest impairment of complex I activity.

Specific enzyme defects are documentable in mendelian conditions, especially clear in "direct" and "indirect" hits of complex I and complex IV. However, universal decrease of all respiratory chain enzymes (except for complex II) typically appears in conditions of MDS and—equally devastating—it typically also characterizes most disorders due to mtDNA translation syndromes. Occasionally, defects in Fe-S assembly proteins show biochemical decreases of three specific respiratory chain enzymes (complex I, complex II, complex III) and of one specific enzyme of the Krebs cycle (aconitase) of which Fe-S are components.

MANAGEMENT

No panacea for respiratory chain dysfunction and no universal therapy for mitochondrial disorders currently exist. Nevertheless, symptomatic pharmacologic treatments (eg, antiepileptic drugs) and surgical remedies (such as blepharoplasty) are useful in prolonging and improving the lives of patients with mitochondrial disease. Exercise therapy has been demonstrated to improve exercise tolerance and quality of life in patients with mitochondrial diseases. Several strategies aimed at curing (or even preventing) mitochondrial diseases have shown promise in vitro or in animals or have produced encouraging preliminary results in humans and are briefly reviewed in the following sections.

Mitochondrial Transfer

For mtDNA-related diseases, many of which are devastating and undiagnosable prenatally, the ultimate goal is to prevent their occurrence altogether via mitochondrial replacement. In this approach, the nucleus of an in vitro–fertilized oocyte from an mtDNA mutation carrier is transferred to an enucleated oocyte from a normal donor: The embryo will have the nDNA of the biologic parents but the mtDNA of a normal mitochondrial donor. In nonhuman primate experiments using oocyte spindle-chromosomal complex transfer, the infants were healthy and devoid of original maternal mtDNA. The same technique was applied to fertilized and unfertilized but parthenogenically activated human oocytes, and the cells were found to develop into normal blastocysts and contain virtually exclusively donor mtDNA. Moreover, only donor mtDNA was detected after stem cell lines from blastocysts were differentiated into neurons, cardiomyocytes, and β cells. Similar results were obtained in the United Kingdom after pronuclear transfer in abnormally fertilized human oocytes developed to the blastocyst stage. Despite ethical concerns, in 2016, the Human Fertilisation and Embryology Authority authorized the use of this technology on a case-by-case basis. The first oocyte mitochondrial replacement procedure with in vitro fertilization has been already performed in a woman carrier who gave birth to a healthy boy with low neonatal mtDNA mutation loads.

Shifting Heteroplasmy

For mtDNA-related disorders, an obvious but challenging goal is to shift heteroplasmy in patients, thereby lowering the mutation load to subthreshold levels. When deprived of glucose and exposed to ketogenic media, cybrids harboring single mtDNA deletions shifted their heteroplasmy level and recovered mitochondrial function, probably through selective mitochondrial autophagy (mitophagy). A genetic approach to heteroplasmic

shifting involves use of restriction endonucleases to eliminate specific pathogenic mutations.

Enhancement of Oxidative Phosphorylation Function

The most obvious therapeutic approach to mitochondrial disorders is to enhance OxPhos function, thereby mitigating both energy crisis (ATP deficit) and oxidative stress (toxic buildup of reactive oxygen species). The compound used almost universally in patients with mitochondrial disease is CoQ_{10}, given the pivotal role of this molecule in electron transport, its antioxidant properties, and its safety even at high doses. Two synthetic analogs of CoQ_{10}—idebenone and parabenzoquinone—seem more promising. Idebenone, a short-chain benzoquinone, has shown mild positive results at 900 mg daily in two studies of patients with LHON. The second compound, a parabenzoquinone labelled EPI-743, has so far been tested only in open studies: This compound at 100 to 400 mg 3 times daily reversed vision loss in four of five patients with LHON, produced clinical improvement in 12 children with various mitochondrial disorders, and arrested or reversed disease progression in 13 children with genetically proven LS.

Elimination of Noxious Compounds

The second logical therapeutic approach to mitochondrial disease is to eliminate the noxious compounds that accumulate in these disorders. To decrease brain lactate in patients with MELAS, we used dichloroacetate, which keeps pyruvate dehydrogenase in the active form and favors lactate oxidation. Unfortunately, this agent had unacceptable neurotoxicity and treatment had to be discontinued. A more promising "detoxifying therapy" seems to be allogeneic hematopoietic stem cell transplantation (AHSCT) aimed at restoring sufficient thymidine phosphorylase activity in patients with MNGIE to normalize the circulating toxic levels of thymidine and deoxyuridine. As of 2012, 9 of 24 patients with MNGIE who had undergone AHSCT were alive and had normal blood thymidine phosphorylase activity, virtually undetectable levels of thymidine and deoxyuridine, and mild clinical improvements; however, transplant-related mortality was unacceptably high. A safety study in a subset of AHSCT in patients with MNGIE is under way to assess if transplants can be performed with low morbidity in mildly to moderately affected individuals.

Small Molecule Therapies

Compassionate use of deoxynucleosides (thymidine and deoxycytidine) has shown promising results in patients with defects of mtDNA maintenance due to TK2 deficiency. A follow-up clinical trial is in progress.

Alteration of Mitochondrial Dynamics

Mitochondrial dynamics could be exploited therapeutically in two opposing ways. Enhancing mitochondrial fission can favor mitophagy, a natural "quality control" function that sequesters and eliminates dysfunctional mitochondria, perhaps through sensing their abnormally low membrane potential. Alternatively, enhancement of mitochondrial fusion and "networking" would allow complementation of "bad" and "good" mitochondria and normalization of overall mitochondrial function.

Although natural mitochondrial proliferation (eg, RRF) is a futile compensatory mechanism, preliminary studies indicate that it may be possible to improve on natural processes by enhancing mitochondrial biogenesis through activation of the transcriptional coactivator PGC-1α AMPK pathway or sirtuin 1. The advantage over disease-induced mitochondrial proliferation, which appears to favor mutated mtDNAs, is that upregulation of mitochondrial biosynthesis increases numbers of all mtDNAs, allowing wild-type genomes to compensate for mutated ones. Encouraging results have been obtained in four mouse models of COX deficiency.

Neurocutaneous Syndromes 145

Marc C. Patterson

KEY POINTS

1. The integument and nervous system both develop from the ectoderm of the fetus. As a result, many developmental disorders of the central nervous system are accompanied by characteristic cutaneous manifestations. These disorders are known as *neurocutaneous syndromes.*
2. Two overlapping subclassifications of neurocutaneous disorders have been proposed: neurocristopathies, which embrace disorders in which cells of neural crest origin develop abnormally or undergo neoplastic transformation, and RASopathies, including disorders associated with mutations of genes in the rat sarcoma/mitogen-activated protein kinase pathway.
3. The diagnosis of neurocutaneous syndromes is based on clinical criteria. Genetic testing is supportive, but owing to the large size of many of these genes, as well as tissue mosaicism, mutations cannot be defined in all patients who clearly have such syndromes.
4. Most of the neurocutaneous syndromes are dominantly inherited and have variable penetrance and highly variable expressivity. Clinicians must be alert to the possibility of such syndromes and thoroughly evaluate potentially affected individuals, in whom manifestations may be subtle.

INTRODUCTION

Several genetic diseases involve both the skin and nervous system. These are called *neurocutaneous disorders* or *neuroectodermatoses.* In the past, they were referred to as the *phakomatoses* (*phakos* is the Greek word for lentil, flat plate, or spot). Many neurocutaneous syndromes are included in other pathologic or genetic groupings. For example, neurofibromatosis (NF) 1 and 2, tuberous sclerosis complex (TSC), Sturge-Weber syndrome, von Hippel-Lindau syndrome, and Waardenburg syndrome are included in the family of neurocristopathies. Neurocristopathies are defined as genetic disorders in which cells derived from the neural crest manifest abnormal development, undergo neoplastic transformation, or both.

The term *RASopathy* refers to disorders in which genes expressed in the rat sarcoma (RAS)/mitogen-activated protein kinase (MAPK) pathway are mutated, resulting in abnormal cell numbers, morphology, location, or ageing. This group includes NF-1, as well as the overlapping phenotypes of Noonan syndrome, Noonan syndrome with multiple lentigines (LEOPARD syndrome), and Legius syndrome. Any part of the central nervous system (CNS) or peripheral nervous system can be affected by these hereditary diseases; their expressivity is quite variable both between and within kindreds.

NEUROFIBROMATOSIS

Introduction

Although NF was first described at least as early as the 17th century and a comprehensive clinical review was published in 1849, the clinical and pathologic phenotypes were first linked by von Recklinghausen in 1882. NF is one of the most common single-gene disorders of the CNS. Cardinal features include multiple cutaneous hyperpigmented marks (*café au lait spots*), multiple neurofibromas and lesions in bone, CNS, peripheral nervous system, or other organs. The best characterized forms are neurofibromatosis type 1 (NF-1; *von Recklinghausen disease* or *peripheral NF* (MIM 162200) and neurofibromatosis type 2 (NF-2; *central NF* or the *bilateral acoustic neuroma syndrome* [MIM 101000]) and schwannomatosis, a phenotype characterized by the presence of multiple schwannomas, associated with intractable pain, without vestibular involvement. The three conditions differ in genetics, pathogenesis, and clinically.

Epidemiology

Both sexes are affected equally, and the condition is found worldwide in all racial and ethnic groups. Incidence figures must be a minimal estimate, because mild cases are often unrecognized.

Molecular Genetics and Pathogenesis

NF-1, NF-2, and schwannomatosis are autosomal dominant conditions; penetrance of NF-1 is almost 100%, but expressivity varies. Mutations account for 50% of new cases. The *NF-1* gene has been mapped to chromosome 17q11.2. The gene product is called *neurofibromin*, a tumor-suppressor gene that acts through the RAS/MAPK pathway. Translocations, large megabase deletions, large internal deletions, small rearrangements, and point mutations all occur in the *NF-1* gene. Although the genotypes differ, the phenotypes are indistinguishable. The marked clinical variability within families having an identical *NF-1* gene mutation equals the variability among families with different *NF-1* gene mutations. The exception occurs with large megabase deletions, associated with cognitive dysfunction and more severe clinical manifestations generally. Mutation inactivates the gene, and, by analogy with other oncogenes, loss of the allelic gene later in life could result in tumor formation. It is not known how the other manifestations of the disease arise. Several potential genetic modifiers in associated signaling pathways have been identified in screening studies.

The *NF-2* gene maps to chromosome 22q12. The gene product is similar to that of the moesin-ezrin-radixin–like protein gene; for this reason, it is called *merlin.* Deletions of the gene have been found in schwannoma and meningioma cells, the major tumors in NF-2 patients. Merlin inhibits the Rac/CDC42-dependent Ser/Thr p21 activated kinase (PAK1), which activates

both Ras transformation and NF-1, through two separate domains. Specific inhibitors of PAK1 selectively inhibit the growth of NF-2–deficient cancer cells, suggesting that PAK1 is essential for the malignant growth of NF-2–deficient cells. Inhibitors of PAK1 might have a future role as therapies for these tumors.

Schwannomatosis has been linked to mutations in three genes: *SMARCB1*, *LZTR1*, and *COQ6*. The *SMARCB1* gene product is a subunit of the SWI/hSHNF chromatin remodeling complex. Mutations in this gene account for about half of familial schwannomatosis but only about 10% of sporadic cases. The *LZTR1* encodes a protein that acts as a tumor suppressor; COQ6 mutations impair the synthesis of coenzyme Q10.

Neuropathology

Dysplasia, hyperplasia, and neoplasia of neural-supporting tissues involve the central, peripheral, and autonomic nervous systems. Visceral manifestations result from hyperplasia of the autonomic ganglia and nerves within the organ. Dysplastic and neoplastic changes also affect skin, bone, endocrine glands, and blood vessels. Developmental anomalies include thoracic meningocele and syringomyelia. Patients affected by NF-1 are more likely than others to have neoplastic disorders, including neuroblastoma, Wilms tumor, leukemia, pheochromocytoma, and sarcomas.

Neoplasms involving the peripheral nervous system and spinal nerve roots include schwannomas and neurofibromas. Intramedullary spinal cord tumors include ependymomas (especially of the conus medullaris and filum terminale) and astrocytomas (although some of these may actually be ependymomas when electron microscopy is used); gangliogliomas are rare. The most common intracranial tumors are hemispheric astrocytomas of any histologic grade from benign to highly malignant; posterior fossa tumors are rare. Pilocytic astrocytic gliomas of the optic nerve and optic chiasm are also characteristic and generally progress very slowly. Bilateral acoustic neuromas and solitary or multicentric meningiomas occur in adults with NF-2.

Symptoms and Signs

There are at least four forms of NF. *Peripheral NF (NF-1)* as described by von Recklinghausen is most common. *Central NF (NF-2)* is manifested by bilateral acoustic neuromas with mild cutaneous changes. *Segmental NF* arises from mosaic-type microdeletions in NF-1; it is characterized by café au lait spots and neurofibromas that are limited, usually affecting an upper body segment. The lesions extend to the midline and include the ipsilateral arm but spare the head and neck. *Cutaneous NF* is limited to pigmentary changes; there are numerous café au lait spots but no other clinical manifestations. One percent to 4% of patients with a mild NF phenotype (café au lait spots only) have a related disorder, Legius syndrome, which is associated with mutations in the *SPRED1* gene in 90% of cases.

The NF-1–Noonan syndrome has the clinical manifestations of NF-1 coupled with a Noonan syndrome phenotype. The clinical features of the Noonan syndrome include ocular hypertelorism, downward-slanting palpebral fissures, webbed neck, low-set ears, and pulmonic stenosis.

NF-1 has protean and progressive manifestations. Families and physicians often anticipate a fate like that of Joseph Merrick (the Elephant Man, who almost certainly had the Proteus syndrome, not NF-1). In reality, many patients with the disease are functionally indistinguishable from normal. Often, they have only cutaneous lesions and are not diagnosed until they see a physician because of a learning disability, scoliosis, or another problem.

FIGURE 145.1 Café au lait macules on the trunk of an infant with neurofibromatosis type 1.

Cutaneous Manifestations

The café au lait macule is the pathognomonic lesion, being present in almost all patients (Fig. 145.1). Six or more café au lait spots larger than 5 mm in diameter before puberty and greater than 15 mm in diameter after puberty are diagnostic. The spots are usually present at birth but may not appear until age 1 or 2 years. Increasing in both size and number during the first decade of life, the macules tend to be less evident after the second decade because they blend into the surrounding hyperpigmented skin. These discrete, tan macules involve the trunk and limbs in a random fashion but tend to spare the face.

Other cutaneous manifestations may include freckles over the entire body, but freckles usually involve the axilla and other intertriginous areas. Larger, darker hyperpigmented lesions are often associated with an underlying plexiform neurofibroma; if this involves the midline, it may indicate the presence of a spinal cord tumor.

Ocular Findings

Pigmented iris hamartomas (Lisch nodules) are pathognomonic and consist of small translucent yellow or brown elevations on slit lamp examination (Fig. 145.2). The nodules increase in number with age and are present in almost all patients older than 20 years.

FIGURE 145.2 Lisch nodules in a patient with neurofibromatosis type 1.

FIGURE 145.3 Left optic nerve glioma on coronal magnetic resonance imaging of the brain.

Neurologic Symptoms

Neurofibromas are highly characteristic lesions and usually become clinically evident at age 10 to 15 years. They always involve the skin, ultimately developing into sessile, pedunculated lesions. The nodules are found on deep peripheral nerves or nerve roots and on the autonomic nerves that innervate the viscera and blood vessels. The lesions increase in size and number during the second and third decades. There may be a few or many thousands. These benign tumors consist of neurons, Schwann cells, fibroblasts, blood vessels, and mast cells. They rarely give rise to any symptoms other than pain as a result of pressure on nerves or nerve roots; however, they may undergo sarcomatous degeneration in the third and fourth decades of life. Neurofibromas involving the terminal distribution of peripheral nerves form vascular plexiform neurofibromas that result in localized overgrowth of tissues or segmental hypertrophy of a limb. Spinal root or cauda equina neurofibromas are often asymptomatic when they are small, but large tumors may cause myelopathy. The number and size of neurofibromas may increase during pregnancy.

Optic gliomas, astrocytomas, acoustic neuromas, neurilemmomas, and meningiomas have a combined frequency of 5% to 10% in all patients with NF. Optic nerve gliomas and other intracranial neoplasms are often evident before age 10 years; acoustic neuromas become symptomatic at about age 20 years. When optic glioma is associated with NF, it commonly involves the optic nerve (Fig. 145.3) or is multicentric; less frequently, it involves the chiasm. Optic nerve glioma must be distinguished from the commonly observed nonneoplastic optic nerve hyperplasia. The optic glioma of NF is slowly progressive and has a better prognosis than similar tumors without this association.

NF-2 is clinically evident at about age 20 years; symptoms include hearing loss, tinnitus, imbalance, and headache. Only a few café au lait spots and neurofibromas are seen. Intracranial and intraspinal neoplasms include meningiomas, schwannomas, and gliomas.

The CNS involvement in NF is highly variable. Macrocephaly, a common clinical manifestation of postnatal origin, is an incidental finding, not related to academic performance, seizures, or neurologic function. Specific learning disabilities or attention deficit disorder, with or without impaired speech, is the most common neurologic complication of NF. Intellectual disability or convulsive disorders each occur in about 5% of the patients. Brainstem tumors associated with NF-1 have a more indolent course than those without NF.

Occlusive cerebrovascular disease is rare but is sometimes seen in children, resulting in acute hemiplegia and convulsions. Magnetic resonance angiography or conventional angiography may demonstrate tapering occlusion of the supraclinoid portion of the internal carotid artery at the origin of the anterior and middle cerebral arteries with associated collaterals in the adjacent basal ganglia (moyamoya disease).

A more severe form of NF-1, often clinically apparent in young children, is due to a contiguous gene deletion on chromosome 17q11 that includes neurofibromin. In addition to the clinical features of NF-1, there are dysmorphic features, major malformations, and intellectual disability.

Skeletal and Limb Manifestations

Skeletal anomalies characteristic of NF include (1) unilateral defects in the posterosuperior wall of the orbit, with pulsating exophthalmos, usually associated with dural ectasia; (2) a defect in the lambdoid with underdevelopment of the ipsilateral mastoid; (3) dural ectasia with enlargement of the spinal canal and scalloping of the posterior portions of the vertebral bodies (also seen in connective tissue disorders such as Marfan and Ehlers-Danlos syndromes); (4) scoliosis, affecting between 21% and 49% of patients with NF-1; (5) pseudarthrosis, especially involving the tibia (5% of cases) and radius; (6) "twisted ribbon" rib deformities; and (7) enlargement of long bones.

Miscellaneous Manifestations

Pheochromocytomas occur in 0.1% to 5.7% of patients with NF-1; they are rare in children. Hypertension may be due to a pheochromocytoma (20%-50% of cases) or a neurofibroma of a renal artery. A population-based study from Finland found a standardized incidence ratio for all forms of cancer of 5.03 in their cohort of NF-1 patients; in addition to intracranial gliomas

and malignant peripheral nerve sheath tumors, these included breast cancer, gastrointestinal stromal tumor, and thyroid cancer. Precocious puberty and, less commonly, sexual infantilism result from involvement of the hypothalamus by glioma or hamartoma. Cystic lesions, malignancy, and interstitial pneumonia are pulmonary complications.

Diagnosis

Diagnosis of NF-1 or NF-2 is based on clinical, radiologic, and pathologic findings as well as the family history. Diagnostic criteria were established by a National Institutes of Health Consensus Conference (**Table 145.1**). Some investigators have suggested updating the criteria to account for new knowledge regarding "anaemic nevi, unidentified bright objects, choroidal hamartomas, and a typical neuropsychological phenotype" in NF-1.

Laboratory Data

Diagnosis is usually made by clinical presentation and family history. Molecular genetic studies are available, but many subjects who meet consensus diagnostic criteria do not have detectable mutations in the NF-1 gene. Most affected individuals have de novo mutations.

All patients and those at risk should receive a tailored evaluation to confirm the diagnosis and assess the extent of disease. A comprehensive evaluation may include psychoeducational and psychometric testing; electroencephalogram; ophthalmologic and audiologic testing; cranial computed tomography (CT), including orbital views; CT of the spine and internal auditory foramina; magnetic resonance imaging (MRI) of brain and spine; and quantitative measurement of 24-hour urinary catecholamines. The MRI of the brain frequently demonstrates areas of signal hyperintensity that may represent areas of abnormal myelination (**Fig. 145.4**); some such lesions reveal themselves as low-grade gliomas over time, mandating periodic surveillance.

TABLE 145.1 Diagnostic Criteria for Neurofibromatosis

Neurofibromatosis Type 1 (Any Two or More)
Six or more café au lait macules Before puberty >5 mm diameter After puberty >15 mm diameter
Freckling in the axillary or inguinal areas
Two or more neurofibromas or one plexiform neurofibroma
A first-degree relative with NF-1
Two or more Lisch nodules (iris hamartomas)
Bone lesion
Sphenoid dysplasia
Thinning of the cortex of long bones with or without pseudarthrosis
Neurofibromatosis Type 2
Bilateral eighth nerve tumor (MRI, CT, or histologic confirmation)
A first-degree relative with NF-2 and a unilateral eighth nerve tumor
A first-degree relative with NF-2 and any two of the following: neurofibroma, meningioma, schwannoma, glioma, or juvenile posterior subcapsular lenticular opacity

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging; NF-1, neurofibromatosis type 1; NF-2, neurofibromatosis type 2.

FIGURE 145.4 Area of signal hyperintensity on axial magnetic resonance imaging of the brain in a patient with neurofibromatosis type 1.

Management

There is no specific treatment for NF, but its manifestations may be ameliorated with early recognition and prompt therapeutic intervention. Learning disabilities should be considered in all children with NF-1 and may be complicated by comorbid conditions (such as attention deficit hyperactivity disorder) that warrant educational therapy or behavioral modification, psychotherapy, and pharmacotherapy. Speech problems require a language evaluation and formal speech therapy, and seizures should be managed with appropriate antiepileptic drugs. Progressive kyphoscoliosis usually requires surgical intervention. Surgery may be necessary for removal of pheochromocytomas and intracranial or spinal neoplasms; cutaneous neurofibromas require extirpation when they compromise function or are disfiguring. Preliminary data suggest that thalidomide might have a role in treating neurofibromas. Radiation therapy is reserved for some CNS neoplasms, including optic glioma. Genetic counseling by a qualified geneticist or genetic counselor is essential, and psychotherapy with family counseling is often indicated.

TUBEROUS SCLEROSIS COMPLEX

Introduction

TSC was first described by von Recklinghausen in 1863. In 1880, Bourneville coined the term *sclérose tubéreuse* for the potato-like lesions in the brain. In 1890, Pringle described the facial nevi, or *adenoma sebaceum*. Vogt later emphasized the classic triad of seizures, intellectual disability, and adenoma sebaceum. TSC (MIM 191440) is a progressive genetic disorder characterized by the development in early life of hamartomas; malformations; and congenital tumors of the CNS, skin, and viscera.

Epidemiology

The incidence of TSC is 1 in 6,000 to 10,000 live births. Clinical surveys suggest a prevalence between 1 in 10,000 and 1 in 170,000. Pulmonary lymphangioleiomyomatosis, progressive and often fatal, occurs almost exclusively in young women.

Genetics

Tuberous sclerosis is an autosomal dominant trait, with a high incidence of sporadic cases and protean clinical expression. This variability is attributed to modifier genes. The defective genes map to chromosome 9q34 (TSC1) and chromosome 16p13.3 (TSC2). TSC1 or TSC2 is mutated in 75% to 85% of TSC patients; no mutation is found in 15%. *Hamartin* is the gene product for TSC1, and *tuberin* is the gene product for TSC2. Hamartin and tuberin form heterodimers that inhibit the mammalian target of rapamycin; phosphorylation is an important aspect of this complex process, which involves over 50 interacting proteins.

Pathology and Pathogenesis

The pathologic changes are widespread and include lesions in the nervous system, skin, bones, retina, kidney, lungs, and other viscera. Multiple small nodules often line the ventricles.

TSC is characterized by the presence of hamartias and hamartomas. Hamartias (from the Greek for "flaw") are malformations in which cells native to a tissue display abnormal architecture and morphology. These lesions do not grow disproportionately for the tissue or organ in which they are found. Hamartomas have the same characteristics but grow excessively for their site of origin. This old concept is valuable in recognizing the proliferative potential of lesions found in TSC. Thus, cortical tubers are hamartias and do not grow excessively, whereas angiomyolipomas are hamartomas that grow disproportionately and may produce symptoms as a consequence.

The brain is usually normal in size, but variable numbers of hard nodules occur on the surface of the cortex. These nodules are smooth, round, or polygonal and project slightly above the surface of the neighboring cortex. They are white, firm to the touch, and of various sizes. Some involve only a small portion of one convolution; others encompass the convolutions of one whole lobe or a major portion of a hemisphere. In addition, there may be developmental anomalies of the cortical convolutions in the form of pachygyria or microgyria. On sectioning of the hemispheres, sclerotic nodules may be found in the subcortical gray matter, the white matter, and the basal ganglia. The lining of the lateral ventricles is frequently the site of numerous small nodules that project into the ventricular cavity. Sclerotic nodules are less frequently found in the cerebellum. The brainstem and spinal cord are rarely involved.

Histologically, the nodules are characterized by a cluster of atypical glial cells in the center and giant cells in the periphery. Calcifications are relatively frequent. Other features include heterotopia, vascular hyperplasia (sometimes with actual angiomatous malformations), disturbances in the cortical architecture, and, occasionally, development of subependymal giant cell astrocytomas (SEGAs). Intracranial giant aneurysm and arterial ectasia are uncommon findings.

The skin lesions are multiform and include the characteristic facial angiofibromas and fibrous plaques, typically localized to the frontal area. The facial lesions are not adenomas of the sebaceous glands (a commonly used misnomer) but rather small hamartomas arising from nerve elements of the skin combined with hyperplasia of connective tissue and blood vessels (angiofibromas). In late childhood, lesions similar to those on the face are found around or underneath the nails (*periungual or subungual fibromas*). Circumscribed areas of hypomelanosis or depigmented nevi (Fig. 145.5) are common in tuberous sclerosis and are often found in infants. Although these depigmented nevi are less specific than the angiofibromas, they are important indications of the diagnosis in infants with seizures. Histologically, the skin appears normal except for the loss of melanin, but ultrastructural studies show that melanosomes are small and have reduced content of melanin.

FIGURE 145.5 Hypopigmented lesions on the thigh of an infant with TSC1, highlighted with ultraviolet light (Woods lamp).

The retinal lesions are small, congenital tumors composed of glia, ganglion cells, or fibroblasts. Glioma of the optic nerve has been reported.

Other lesions include cardiac rhabdomyoma; renal angiomyolipoma, renal cysts, and, rarely, renal carcinoma; cystic disease of the lungs and pulmonary lymphangioleiomyomatosis; hepatic angiomas and hamartomas; skeletal abnormalities with localized areas of osteosclerosis in the calvarium, spine, pelvis, and limbs; cystic defects involving the phalanges; and periosteal new bone formation confined to the metacarpals and metatarsals.

Symptoms and Signs

The cardinal features of tuberous sclerosis are skin lesions, convulsive seizures, and disability. The disease is characterized by variable expressivity of the clinical manifestations and is often age related: the symptomatic neonate with cardiac rhabdomyoma and heart failure; the infant with hypomelanotic macules and infantile spasms; preschool and school-age children with angiofibromas, developmental delay, learning disability or intellectual disability, and seizures; and adults with migrational dermatologic lesions, subungual fibromas, seizures, and often intellectual disability.

Cutaneous Findings

Depigmented or hypomelanotic macules are the earliest skin lesion. They are present at birth, persist through life, and may be found only with a Wood lamp examination. The diagnosis is suggested if there are three or more macules measuring 1 cm or more in length. Numerous small macules sometimes resemble confetti or depigmented freckles. Most macules are leaf shaped, resembling the leaf of the European mountain ash tree and sometimes following a dermatomal distribution. Facial angiofibromas never present at birth, but are clinically evident in more than 90% of affected children by age 4 years. At first, the facial lesion is the size of a pinhead and red because of the angiomatous component. It is distributed symmetrically on the nose and cheeks in a butterfly distribution. The lesions may involve the forehead and chin but rarely involve the upper lip. They gradually

increase in size and become yellowish and glistening. *Shagreen patches*, connective tissue hamartomas, are also characteristic. Rarely present in infancy, the patches become evident after age 10 years. Usually found in the lumbosacral region, shagreen patches are yellowish-brown elevated plaques that have the texture of pigskin (from which the name originated in French). Other skin lesions include café au lait spots, small fibromas that may be tiny and resemble coarse gooseflesh, and ungual and periungual fibromas that appear after puberty.

Neurologic Findings

Epileptic spasms are the characteristic seizures in young infants and, when associated with hypopigmented macules, are diagnostic of tuberous sclerosis. The older child or adult has generalized tonic-clonic or focal seizures. There is a close relationship between the onset of seizures at a young age and intellectual disability. Intellectual disability rarely occurs without clinical seizures, but intellect may be normal, despite seizures. Other than delayed acquisition of developmental milestones, intellectual impairment, or nonspecific language or coordinative deficiencies, the formal neurologic examination is typically nonfocal. TSC is strongly associated with autism spectrum disorder.

Ophthalmic Findings

Hamartomas of the retina or optic nerve are observed in about 50% of patients. Two types of retinal lesions are seen on funduscopy: first, the easily recognized calcified hamartoma near or at the disc with an elevated multinodular lesion that resembles mulberries, grains of tapioca, or salmon eggs, and second, the less distinct, relatively flat, smooth-surfaced, white or salmon-colored, circular or oval lesion located peripherally in the retina. Nonretinal lesions may range from the specific depigmented lesion of the iris, to nonspecific, nonparalytic strabismus; optic atrophy; visual-field defects; or cataracts.

Visceral and Skeletal Findings

Renal lesions include hamartomas (angiomyolipomas) and hamartias (renal cysts). Typically, both are multiple, bilateral, and usually innocuous and silent. Renal angiomyolipomas grow and occasionally bleed, but most can simply be followed with annual CT scans. Renal cell carcinoma is a rare complication in the older child or adult. In one series, 50% of patients with cardiac rhabdomyoma had tuberous sclerosis. Often asymptomatic, this cardiac tumor may be symptomatic at any age and in infancy can (rarely) result in death.

Pulmonary hamartomas consisting of multifocal alveolar hyperplasia associated with cystic lymphangioleiomyomatosis occur in fewer than 1% of patients. These become symptomatic (often with a spontaneous pneumothorax) in women in the third or fourth decade and are progressive and often lethal. Hamartomatous hemangiomas of the spleen and racemose angiomas of the liver are rare and usually asymptomatic. Sclerotic lesions of the calvarium and cystic lesions of the metacarpals and phalanges are asymptomatic. Enamel pitting of the deciduous teeth and gingival fibromas may aid in diagnosis.

Laboratory Data

An MRI of the brain is the cornerstone of diagnosis of TSC. Cortical tubers may be hypo- or isointense on T1-weighted images and show varying patterns of hyperintensity on T2 and fluid-attenuated inversion recovery sequences; calcification may occur over time (Fig. 145.6). Subependymal nodules are common and most calcify over time; radial bands of hyperintense signal from the ventricles to the cortex are characteristic of TSC. SEGAs arise from the caudothalamic groove and may obstruct the ipsilateral foramen of Monro; these tumors most often present in the second decade. Positron emission tomography often reveals hypometabolic regions that are not obviously abnormal on MRI, indicating a more extensive disturbance of cerebral function.

FIGURE 145.6 Multiple cortical tubers in an 18-year-old with TSC1.

Visceral lesions are best assessed with imaging studies. Cardiac rhabdomyomas, easily visualized on echocardiography, are frequent in neonates and typically regress over time, whereas renal angiomyolipomas may gradually enlarge and produce symptoms by obstructing the collecting system or bleeding. They are best monitored with ultrasound or CT.

Pulmonary lymphangioleiomyomatosis may be detected on routine chest x-rays, but chest CT is more sensitive.

The electroencephalogram (EEG) is often abnormal, especially in patients with clinical seizures. Abnormalities include slow-wave activity and epileptiform discharges such as hypsarrhythmia, focal or multifocal spike or sharp-wave discharges, and generalized spike-and-wave discharges. Routine laboratory tests of blood and urine are usually normal, except if there is renal dysfunction, including bleeding from angiolipomas.

Diagnosis

Clinical diagnosis is possible at most ages. In infancy, three or more characteristic depigmented cutaneous lesions suggest the diagnosis, which is reinforced by the presence of epileptic spasms. In the older child or adults, the diagnosis is made by the triad of tuberous sclerosis: facial angiofibromas, epilepsy, and intellectual disability. Retinal or visceral lesions may be diagnostic. The disease, however, is noted for its protean manifestations, and the family history may be invaluable in establishing the diagnosis, which is often reinforced by CT or MRI lesions. Antenatal diagnosis of TSC by fetal ultrasound and MRI is suggested by the presence of a cardiac rhabdomyoma and cortical tubers. Prenatal molecular diagnosis is available for both TSC1 and TSC2.

TABLE 145.2 Diagnostic Criteria for Tuberous Sclerosis Complex

A. Genetic Diagnostic Criteria
The identification of either a TSC1 or TSC2 pathogenic mutation in DNA from normal tissue is sufficient to make a definite diagnosis of tuberous sclerosis complex (TSC). A pathogenic mutation is defined as a mutation that clearly inactivates the function of the TSC1 or TSC2 proteins (eg, out-of-frame indel or nonsense mutation), prevents protein synthesis (eg, large genomic deletion), or is a missense mutation whose effect on protein function has been established by functional assessment (www.lovd.nl/TSC1, www.lovd/TSC2). Other TSC1 or TSC2 variants whose effect on function is less certain do not meet these criteria and are not sufficient to make a definite diagnosis of TSC. Note that 10%-25% of TSC patients have no mutation identified by conventional genetic testing, and a normal result does not exclude TSC or have any effect on the use of clinical diagnostic criteria to diagnose TSC.
B. Clinical Diagnostic Criteria
Major Features
1. Hypomelanotic macules (≥3, at least 5-mm diameter)
2. Angiofibromas (≥3) or fibrous cephalic plaque
3. Ungual fibromas (≥2)
4. Shagreen patch
5. Multiple retinal hamartomas
6. Cortical dysplasias[a]
7. Subependymal nodules
8. Subependymal giant cell astrocytoma
9. Cardiac rhabdomyoma
10. Lymphangioleiomyomatosis (LAM)[b]
11. Angiomyolipomas (≥2)[b]
Minor Features
1. "Confetti" skin lesions
2. Dental enamel pits (>3)
3. Intraoral fibromas (≥2)
4. Retinal achromic patch
5. Multiple renal cysts
6. Nonrenal hamartomas
Definite diagnosis: two major features or one major feature with ≥2 minor features
Possible diagnosis: either one major feature or ≥2 minor features

[a]Includes tubers and cerebral white matter radial migration lines.
[b]A combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis.

The differential diagnosis includes other neurocutaneous syndromes that are differentiated by their characteristic skin lesions. Multisystem involvement may complicate the diagnosis of tuberous sclerosis. The Tuberous Sclerosis Complex Consensus Conference has published diagnostic criteria (Table 145.2).

Course and Prognosis

Mild or solely cutaneous involvement often follows a static course, whereas patients with the full-blown syndrome have a progressive course with increasingly frequent and intense seizures and cognitive impairment. The child with epileptic spasms that are not promptly controlled is at great risk for intellectual disability. Brain tumor, status epilepticus, renal insufficiency, cardiac failure, or progressive pulmonary impairment can lead to premature death.

Management

Everolimus, a derivative of rapamycin, has been approved for the treatment of SEGAs that are not suitable for surgery. The initial dose is based on body surface area as follows: 2.5 mg once daily for body surface area 0.5 to 1.2 m^2; 5 mg once daily for 1.3 to 2.1 m^2; 7.5 mg once daily for greater than or equal to 2.2 m^2 and is subsequently adjusted based on serum levels, aiming for a trough concentration of 5 to 10 ng/mL. The drug is also being used for off-label indications, including topical application for angiofibromas and for adjunctive treatment of intractable epilepsy. The efficacy of the agent for these purposes has not yet been established in clinical trials. Everolimus has a number of adverse effects related to its immunosuppressive actions and should be administered with careful monitoring. The cutaneous lesions do not compromise function, but cosmetic surgery may be indicated for facial angiofibromas or large shagreen patches. Epileptic spasms respond to corticosteroid or corticotropin therapy; currently, vigabatrin (25 mg/kg/dose twice a day initially, maximum 75 mg/kg/dose twice a day) is the drug of choice. Focal and generalized seizures are treated with appropriate antiseizure drugs. Patients with focal seizures and minimal developmental delay may experience long-term seizure control following surgical resection of epileptogenic tubers. Progressive cystic renal disease often responds to surgical decompression, but with renal failure, dialysis or renal transplantation may be necessary. Cardiac rhabdomyomas are rarely symptomatic but may be managed medically with standard therapy for arrhythmias or cardiac failure. Surgery is rarely required. Progressive pulmonary involvement is an indication for respiratory therapy, but response is poor and most patients die a few years after the onset of this complication without lung transplantation.

ENCEPHALOTRIGEMINAL ANGIOMATOSIS

Introduction

Encephalotrigeminal angiomatosis (*Sturge-Weber-Dimitri syndrome*; MIM 185300) is manifested by a cutaneous vascular port-wine nevus of the face, contralateral hemiparesis and hemiatrophy, glaucoma, seizures, and intellectual disability. The condition is attributed to partial persistence of a primitive embryonic vascular plexus that develops around the cephalic portion of the neural tube 6 weeks after conception and under the ectoderm in the region destined to become facial skin. In encephalotrigeminal angiomatosis, the vascular plexus persists beyond the ninth week, when it normally regresses. Variability in this process accounts for unilateral or bilateral involvement and also for an incomplete syndrome characterized by leptomeningeal angiomatosis without facial involvement.

Epidemiology

The syndrome occurs in 1:20,000 to 1:50,000 live births.

Genetics

Almost all patients with encephalotrigeminal angiomatosis, and with nonsyndromic port wine stains, carry somatic mosaic activating mutations in the *GNAQ* gene. Mutations in this gene lead to abnormal signaling between G-protein–coupled receptors and downstream effectors. Similar mechanisms have been described in the Proteus and McCune-Albright syndromes.

Neuropathology

The occipital lobe is most often affected, but lesions may involve the temporal and parietal lobes or the entire cerebral hemisphere. Atrophy is characteristically unilateral and ipsilateral to the facial nevus. Leptomeningeal angiomatosis with small venules fills the subarachnoid space. Calcification of the arteries on the surface of the brain and intracerebral calcifications of small vessels are seen. Recent studies have associated focal cortical dysplasia with medically intractable epilepsy in encephalotrigeminal angiomatosis, with important implications for early surgical intervention.

Symptoms and Signs

Facial nevus and a neurologic syndrome of seizures, hemiplegia, intellectual disability, and glaucoma are characteristic. Typically, other than the facial nevus, the child has normal function for months or years. The subsequent clinical course is highly variable.

Cutaneous Manifestations

The port-wine facial stain, or nevus flammeus, involves variable portions of the face and neck. Most commonly involving the forehead, the nevus may involve one-half of the face and may extend to the neck. The nevus may cross or fall short of the midline. Bilateral facial lesions are seen in about 15% of cases (**Fig. 145.7**). Recent studies have suggested that the distribution of the nevus flammeus conforms more closely to the embryonic circulation rather than the divisions of the trigeminal nerve, as previously thought; a nevus involving any part of the forehead is the best clinical indicator of adverse outcome, including glaucoma, seizures, and abnormal development.

Neurologic Manifestations

Epilepsy is the most common neurologic manifestation, usually starting in the first year of life with focal or generalized motor or focal dyscognitive seizures. Often refractory to antiseizure medications, the focal motor seizures, hemiparesis, and hemiatrophy are contralateral to the facial nevus. Onset of seizures before age 2 years and refractory epilepsy has prognostic significance; these patients are more likely to be intellectually impaired. Intellectual disability often becomes more apparent over time.

Ophthalmologic Manifestations

Raised intraocular pressure with glaucoma and buphthalmos occurs in approximately 30% of patients. Buphthalmos, congenital enlargement of the eye, is more common than glaucoma and results from antenatal intraocular hypertension. Homonymous hemianopia, a common visual-field complication, is typically associated with occipital lobe involvement. Other congenital anomalies include coloboma of the iris and deformity of the lens.

Laboratory Data

An MRI with contrast-enhanced fluid-attenuated inversion recovery sequences is the most sensitive noninvasive technique to identify leptomeningeal involvement and cortical atrophy (**Fig. 145.8**). Fluorodeoxyglucose–positron emission tomography may be helpful in predicting seizure control and cognitive outcome: In a study of 13 children, patients with mild asymmetry of glucose uptake had worse cognitive function than those with marked asymmetry, suggesting that functional reorganization

FIGURE 145.7 Bilateral port-wine stain in an infant with Sturge-Weber syndrome.

FIGURE 145.8 Gadolinium-enhanced axial magnetic resonance imaging of the brain (patient shown in **Fig. 145.7**), demonstrating meningeal enhancement, and bilateral, asymmetric, cortical atrophy.

of the cortex more readily occurs with more severe injury. The capillaries over the affected hemisphere are homogeneously increased, the superficial cortical veins are markedly decreased, and the superior sagittal sinus may be diminished or not seen.

The EEG shows low amplitude over the affected areas, and this electrical suppression correlates with the degree of intracranial calcification. The remainder of the hemisphere may show epileptiform activity. The EEG evolves over time, with increasing epileptiform activity, but these electrical changes do not correlate with clinical or seizure severity.

Diagnosis

The diagnosis is based on the facial vascular port-wine nevus flammeus and one or more of the following: seizures, contralateral hemiparesis and hemiatrophy, intellectual disability, and ocular findings of glaucoma or buphthalmos. Meningeal involvement is usually obvious on MRI. Rarely, Sturge-Weber-Dimitri syndrome may occur with the neurologic syndrome and the typical meningeal involvement, absent the facial nevus. Encephalotrigeminal angiomatosis must be distinguished from other vascular malformation syndromes, including Klippel-Trenaunay and Parkes Weber syndromes, both of which feature combined vascular malformations, in contrast to the pure capillary lesions of encephalotrigeminal angiomatosis. The identification of GNAQ mutations provides a means of molecular confirmation in biopsies of affected tissue.

Management

The facial nevus rarely requires early cosmetic therapy. Later, this blemish can be covered with cosmetics or permanently treated with laser therapy. Seizures may be difficult to control with antiseizure medications. Children with medically intractable seizures often respond to hemispherectomy, even when hemiplegia is present. Physical and occupational therapies are indicated for the hemiparesis. Educational therapy and placement in special education are important for learning-disabled or intellectually impaired patients; vocational training is essential in affected older children and young adults. Behavioral problems are common and include mood disorder, disruptive behavior disorder, and adjustment disorder in children, and substance-related disorder in adults. Prophylactic daily low-dose aspirin to prevent venous thrombosis is controversial but can be considered if there are recurrent transient ischemic episodes. Yearly monitoring for glaucoma is recommended for all patients and, if present, should be treated aggressively.

INCONTINENTIA PIGMENTI

Introduction

Incontinentia pigmenti (IP; MIM 308300), described by Bloch and Sulzberger, is a genetic disorder affecting the skin in a characteristic manner and also involving the brain, eyes, nails, and hair.

Genetics

IP is an X-linked dominant condition that is lethal in males. Mutations in the *NEMO/IKKγ* gene at Xq28 cause the disease. The *NEMO/IKKγ* is an essential component of the newly discovered nuclear factor kappa B (NF-κB) signaling pathway. When activated, NF-κB controls the expression of multiple genes, including cytokines and chemokines, and protects cells against apoptosis. The *NEMO/IKKγ* deficiency causes the phenotypic expression of the disease via the NF-κB pathway.

Sporadic disease has also appeared in girls with no family history of the disease. In these cases, there is a translocation with a breakpoint at Xp11.21. Some patients and some families do not map to either site, implying *locus heterogeneity*, with still more gene loci to be discovered.

Incontinentia pigmenti achromians (IPA, or hypomelanosis of Ito; MIM 146150) resembles IP in that the pigmentary changes respect the lines of Blaschko, but it is otherwise an unrelated syndrome. Blaschko lines are not ordinarily visible, but several cutaneous disorders follow parallel linear streaks. A pregnant woman with IP runs a 25% risk of a spontaneous miscarriage (the affected son); 50% of her infant daughters will be affected and will have the disease. Daughters are likely to be more severely affected than their mothers.

Neuropathology

The neuropathologic findings are nonspecific and include cerebral atrophy with microgyria, focal necrosis with formation of small cavities in the central white matter, and focal areas of neuronal loss in the cerebellar cortex.

Cutaneous Findings

One-half of affected infants have the initial linear vesicobullous lesions at birth, and most of the remaining children show the lesions in the first 2 weeks of life. The lesions may be confused with those of neonatal herpes simplex. About 10% are delayed, appearing as late as age 1 year. The skin lesions can recur and ultimately may undergo a characteristic change to linear verrucous and dyskeratotic growth, usually between the second and sixth weeks of life (Fig. 145.9); pigmentary changes appear between 12 and 26 weeks. Some infants may show the pigmentary lesions at birth without further cutaneous progression. The pigmentation involves the trunk and limbs, is slate gray-blue or brown, and is distributed in irregular marbled or wavy lines (Fig. 145.10). With age, the pigmentary lesions fade and become depigmented with atrophic skin changes.

FIGURE 145.9 Linear, verrucous/dyskeratotic skin lesions in an infant with incontinentia pigmenti.

FIGURE 145.10 Pigmented lesions of the trunk in an infant with incontinentia pigmenti.

Neurologic, Ophthalmic, and Other Symptoms

About 20% of affected children have a neurologic syndrome that may include slow motor development; pyramidal tract dysfunction with spastic hemiparesis, quadriparesis, or diplegia; intellectual disability; and seizures. Infants may present with epileptic spasms.

Strabismus, cataracts, and severe visual loss occur in about 20% of affected children. Retinal vascular changes may result in blindness with ectasia, microhemorrhages, avascularity, and later, retinal pigmentation and atrophy.

Partial or total anodontia and peg-shaped teeth are characteristic of IP. Partial or complete diffuse alopecia with scarring and nail dystrophy may also occur.

Laboratory Data

Eosinophilia, as high as 65%, is often seen in infants younger than age 1 year, together with an associated leukocytosis. Eosinophils are also found in the vesicobullous lesions and in affected dermis.

Management

There is no specific treatment for IP, and management is directed at complications, such as anticonvulsants for seizures. One report suggested that steroid therapy improved neurologic manifestations in a neonate with multiple cerebral infarctions complicating IP, but there are no controlled data to substantiate this effect. Awareness of the ocular manifestations is essential, because laser coagulation of avascular retina prevents blindness.

INCONTINENTIA PIGMENTI ACHROMIANS (HYPOMELANOSIS OF ITO)

Introduction

IPA is a syndrome of regions of cutaneous hypopigmentation that conform to the lines of Blaschko, first described by the German dermatologist in 1901, which define the cutaneous distribution of many hereditary dermatoses and acquired inflammatory disorders. The pattern is believed to result from functional autosomal mosaicism transmittable through the action of retrotransposons. IPA is associated with variable involvement of other body systems, particularly the nervous system. It is perhaps best considered a phenotype, rather than a disease, because there are many potential etiologies.

Epidemiology and Genetics

IPA is found in all races and sexes and is a syndrome with multiple etiologies.

Cases of IPA with an identifiable cause are associated with somatic mosaicism for chromosomal trisomies; as many as 90% of affected individuals have neurologic manifestations, including developmental delay, intellectual disability, seizures, and autism spectrum disorder.

Pathogenesis and Pathology

The pathogenesis of this disease is similar to that of other neurocutaneous disorders. Migration of neural cells to the brain and melanoblasts to the skin from the neural crest occurs between 3 and 6 months' gestational age. A disturbance of this migration results in both brain and cutaneous pigmentary disease.

The hypopigmented skin lesions are characterized by a decrease in the number of dopa-positive melanocytes and decreased pigment production in the basal layer of the epidermis.

Clinical Manifestations

In infancy, hypopigmented skin lesions appear as whorls or streaks that follow the lines of Blaschko. This lesion is the negative image of IP. In later childhood, affected areas tend to return to normal skin color. The cutaneous lesion is often associated with developmental and neurologic abnormalities with hypotonia, pyramidal tract dysfunction, intellectual disability (approximately 80%), and seizures. Ophthalmologic disorders, including strabismus, optic atrophy, microphthalmia, tessellated fundus (a normal fundus with a pigmented choroid that creates the appearance of dark polygonal areas between choroidal blood vessels), eyelid ptosis, and heterochromia iridis, are also present. Hair, teeth, and the musculoskeletal system may also be affected.

Diagnosis and Laboratory Data

Because there is no pathognomonic laboratory test, diagnosis is clinical. Investigation for chromosomal mosaicism, with karyotyping of blood, fibroblasts, and hair bulbs, should be considered in all cases.

Management

The whorled, marble-cake hypopigmented skin lesions do not require any treatment. Therapy is directed toward the associated complications, such as antiseizure drugs, and specialized educational facilities for the learning- or intellectually-disabled child.

146 Spinal Muscular Atrophies of Childhood

Basil T. Darras, Richard S. Finkel, and Darryl C. De Vivo

KEY POINTS

1. Clinical subtypes of spinal muscular atrophy (SMA) classified by maximal functional status achieved are type I ("nonsitters"), type II ("sitters"), and type III ("walkers").
2. Type IV SMA is a mild phenotype with onset during early adult or middle age. All SMA types show a spectrum of severity within each subgroup.
3. Non–5q13-associated SMA is a heterogeneous group of motor neuron diseases with clinical characteristics usually distinct from classic SMA.
4. Ninety-five percent to 98% of SMA patients have deletions of the *SMN1* gene. The remainder are compound heterozygotes or have undergone gene conversions from *SMN1* to *SMN2*.
5. Correlation between *SMN2* copy number and phenotype severity cannot predict clinical severity, especially with the intermediate forms of the disease.
6. The justification of adding newborn screening for the genetic identification of presymptomatic individuals with SMA has been demonstrated.
7. Recent data suggest the pathologic effects of reduced survival motor neuron protein are also observed distally, at the neuromuscular junctions.
8. Therapeutic efforts include *SMN1* gene replacement and pharmaceuticals to upregulate *SMN2* expression.
9. New treatments for symptomatic patients with SMA provide some degree of rescue, with improved survival and motor function, but are not a cure.

INTRODUCTION

In the early 1890s, the Austrian clinician Guido Werdnig at the University of Graz, Austria, and the German clinician Johann Hoffmann in Heidelberg, Germany, described an infantile onset neuromuscular disorder causing progressive muscular weakness associated with loss of anterior horn cells in the spinal cord and early death. The spinal muscular atrophies (SMAs) have since been defined as a group of genetic disorders characterized by progressive muscle weakness and atrophy, associated with degeneration of spinal and, in the most severely affected patients, lower bulbar motor neurons. The most common of these disorders, and the leading cause of infant mortality, is classic proximal SMA, which is found in all populations and diagnosed more frequently in infants and children than in adults.

Classic SMA results from homozygous deletions or mutations involving the "survival motor neuron" (*SMN*) gene. Two *SMN* genes, designated *SMN1* and *SMN2*, are present on each chromosome 5, as the result of an inverted duplication at locus 5q13 (**Fig. 146.1**). The duplicated *SMN2* gene is differentiated from *SMN1* by 5-13 nucleotide changes, one of which is essential in creating an exonic splicing silencer in exon 7, leading to exclusion of exon 7 in most transcripts and diminished production (5%-10%) of full-length functional SMN protein. Most patients with 5q proximal SMA harbor homozygous deletions involving exon 7 of the *SMN1* gene, and all patients have at least one *SMN2* copy.

The role of the SMN protein is still under active investigation, but there is a rough correlation between *SMN2* gene copy number, which varies normally in the population, the level of SMN protein, and severity of disease. Abnormalities of the neuromuscular junction have been noted in animal models, and abnormal muscle development in the most severely affected patients.

EPIDEMIOLOGY

The incidence of SMA has been estimated at 1 in 6,000 to 11,000 live births or about 7.8 to 10 per 100,000 live births and at 4.1 per 100,000 live births for SMA type I. The estimated pan-ethnic disease frequency is approximately 1 in 11,000. The carrier frequency for mutations in the *SMN1* gene has been estimated to be highest in Caucasians (1:47) and lowest in African Americans (1:72). Ashkenazi Jews (1:67), Asians (1:59), and Hispanics (1:68) are of intermediate frequency.

CLINICAL CHARACTERISTICS

Although most patients with SMA have deletions or mutations involving the *SMN1* gene, there is a range of phenotypic severity that permits division into four broad clinical subtypes. It is recognized that the subtypes represent a phenotypic continuum extending from the very severe, with onset in utero, to the very mild, with onset during adulthood; there is also a spectrum of severity within each of these subgroups (**Table 146.1**). For the purposes of clinical classification, or of guidelines developed for standards of care, the "maximal functional status achieved" approach, which classifies type I patients as "nonsitters," type II patients as "sitters," and type III patients as "walkers," has been used. Patients with a mild phenotype and onset during middle or late age are classified as type IV. The age at onset is also considered in the classification, but because of potential overlap between subtypes and the difficulty in accurately determining the onset of symptoms, it has not been considered as the sole determinant of disease subtype.

Type I Spinal Muscular Atrophy

Patients with type I SMA, also known as *Werdnig-Hoffmann disease*, present within the first 6 months of life. SMA type I has

FIGURE 146.1 Schematic diagram of human *SMN1* and *SMN2* genes on chromosome 5. Patients with spinal muscular atrophy have deletions or mutations in both copies of *SMN1*. A C-to-T transition at position 6 of *SMN2* creates an exonic splicing suppressor (ESS) that leads to skipping of exon 7 during transcription and production of truncated, nonfunctional SMN protein. However, a small amount (5%-10%) of full-length messenger RNA is produced from the *SMN2* gene, resulting in functional, full-length SMN protein. AA, amino acids. (Reprinted with permission from Darras BT, Markowitz JA, Monani UR, De Vivo DC. Spinal muscular atrophies. In: Darras B, Jones HR Jr, Ryan M, De Vivo DC. *Neuromuscular Disorders of Infancy, Childhood, and Adolescence: A Clinician's Approach*. San Diego, CA: Academic Press: 2015;117-145: Fig 1, p. 118.)

been further subdivided into three groups: type IA with symptoms of hypotonia at birth or onset within the neonatal period, type IB with onset of symptoms prior to age 3 months, and type IC with onset between ages 3 and 6 months. Infants with SMA type I have progressive proximal weakness that affects the legs more than the arms. They have poor head control, hypotonia that causes them to assume a "frog-leg" and "jug-handle" arm posture when lying and to "slip through" on vertical suspension, and areflexia. They are never able to sit ("nonsitters") (see **Table 146.1**). There is also weakness of the intercostal muscles with relative sparing of the diaphragm, producing a bell-shaped chest and a pattern of paradoxical or "belly" breathing. Infants with type I SMA also exhibit tongue fasciculations, difficulty swallowing, risk of aspiration, and failure to thrive. Other cranial nerves are not as affected, although facial weakness does occur at later stages of the disease. Cognition is normal, and they are often noted at diagnosis to have a bright, alert expression that contrasts with their generalized weakness. Sensation is preserved. Infants with type I SMA usually develop respiratory failure by age 2 years, or much earlier, and in the past, most did not survive past age 2 years. Improvement in pulmonary and nutritional support and orthopedic management over the past three decades has significantly improved survival of type I patients but has not changed the progressive decline in motor function. Until the advent of the new therapeutics, these patients failed to improve in motor or respiratory function from the day of diagnosis even with maximal supportive care. Multidisciplinary standard of care initiatives were convened in 2006 and 2017, resulting in published guidelines. These efforts reflect more expert opinion than data from the literature and need to be individualized based on the specifics of the patient, the resources available, and the parents' preferences. There has been a growing trend to provide such supportive care in a proactive way rather than a reactive one. For example, the use of a cough-assist device is often recommended shortly following diagnosis and not waiting for an ineffective cough to evolve.

Type II Spinal Muscular Atrophy

This intermediate form of SMA was first reported in 1893 at the University of Edinburgh, United Kingdom, and described again by Byers and Banker in 1961 and in detail by Dubowitz

TABLE 146.1 Clinical Classification of Spinal Muscular Atrophy[a]

SMA Type	Other Names	Age at Onset	Life Span	Highest Motor Milestone Achieved	Other Features	Proportion of Total SMA (%)
Type IA	Prenatal, congenital SMA, Werdnig-Hoffmann disease	Prenatal	<6 mo	Mostly unable to achieve motor milestones	• Severe weakness at birth • Profound hypotonia • Facial diplegia • Areflexia • Early respiratory failure • Joint contractures	60[b]
Type IB, type IC	Werdnig-Hoffmann disease, severe SMA ("nonsitters")	Type IB (0-3 mo) Type IC (3-6 mo)	<2 y without respiratory support	Never sits supported	• Weakness • "Frog leg" posture, hypotonia • Tongue fasciculations • Hyporeflexia, areflexia • Suck and swallow difficulties • Respiratory failure	60
Type II	Intermediate SMA ("sitters"), Dubowitz disease	6-18 mo	>2 y ~70% alive at 25 y of age	Sits independently, never stands or walks	• Proximal weakness, hypotonia • Postural hand tremor • Hyporeflexia • Average or above average intellectual skills by adolescence • Scoliosis	27
Type III	Kugelberg-Welander disease, mild SMA ("walkers")	>18 mo Type IIIA (prior to 3 y) Type IIIB (after 3 y)	Almost normal	Stands and walks	• May have hand tremor • Resembles muscular dystrophy	12
Type IV	Adult SMA	>21 y	Normal	Normal		1

Abbreviation: SMA, spinal muscular atrophy.
[a]Modified with permission from Markowitz JA, Singh P, Darras BT. Spinal muscular atrophy: a clinical and research update. *Pediatr Neurol*. 2012;46:1-12.
[b]SMA types IA, IB, and IC collectively have a 60% proportion of total incidence of SMA.

in 1964. Patients with type II SMA, also known as *intermediate SMA* or *Dubowitz disease*, are able to sit unsupported at some point ("sitters") but are never able to stand alone or walk (see Table 146.1). Symptom onset is typically between ages 6 and 18 months. They have progressive proximal weakness affecting legs more than arms, hypotonia, and areflexia. Tongue fasciculations are seen in about half of patients. Nearly all type II patients develop progressive scoliosis that, in combination with intercostal muscle weakness, results in significant restrictive lung disease as they grow older. They develop joint contractures and can have ankylosis of the mandible. They exhibit tremor, or polyminimyoclonus, of the hands. Although their body mass index may be low (at the 3rd percentile or less when compared with normal children), the high-functioning, nonambulatory patients have a higher relative fat mass index and are at risk for becoming overweight. Cognition is normal, and verbal intelligence may be above average. In a study done on 240 type II patients, survival rates were found to be 98.5% at 5 years and 68.5% at 25 years. Patients may live into the third decade, but life expectancy is shortened due to the risk of respiratory compromise.

Type III Spinal Muscular Atrophy

In 1956, Kugelberg and Welander described a much milder form of SMA characterized by prolonged ambulation. Patients with type III SMA, also known as *Kugelberg-Welander disease*, are able to stand alone and walk at some point ("walkers"). The onset of symptoms occurs after age 18 months; it has further been subdivided into type IIIA (onset between ages 18 months and 3 years) and type IIIB (onset after age 3 years). They have progressive proximal weakness affecting legs more than arms and may ultimately need to use a wheelchair, but they generally develop little to no respiratory muscle weakness or severe scoliosis. Loss of ambulation increases the risk of these complications. They may have tremor or polyminimyoclonus of the hands. Sometimes, the calves of these patients can be prominent, and hence, type III SMA can be confused with Becker muscular dystrophy. Life expectancy is not significantly different compared with the normal population (see Table 146.1).

Outliers

The most severe form of SMA, type 0 in certain reports, presents with onset in utero and with severe weakness, joint contracture, and need for respiratory and feeding support at birth. At the other end of the spectrum, milder adult-onset SMA, or type IV SMA, has also been described with onset of symptoms after age 21 years and essentially normal life span. Most patients with the SMA type IA and IV phenotypes have homozygous deletions of exon 7 in *SMN1*, but as it is discussed in the "Genetics" section, the *SMN2* copy number is usually only one in SMA type IA and four to five in adult SMA type IV.

Other "Spinal Muscular Atrophies"

The non–5q13-associated SMAs are a heterogeneous group of motor neuron diseases associated with mutations in several different genes (eg, X-linked and autosomal dominant or recessive SMAs), distal or segmental SMAs, or distal hereditary motor neuropathies. Patients with these disorders generally have some clinical characteristics that differentiate them from those with 5q13-associated or classic SMA. The differential diagnosis of SMA is detailed in Table 146.2.

TABLE 146.2 Differential Diagnosis of 5q Spinal Muscular Atrophy[a]

Spinal Cord Disorders
Neoplasms (SMA types I, II, III)
Other myelopathies (SMA types I, II, III)
Other Motor Neuron Disorders
SMARD1 (SMA type I)
Juvenile muscular atrophy of distal upper extremity (Hirayama disease)
Fazio-Londe disease, Brown-Vialetto-van Laere syndrome
Other non-5q SMAs (SMA types I, II, III)
Juvenile ALS (SMA type III)
Neuropathies
Congenital hypomyelinating or axonal neuropathies (SMA types I, II)
Hereditary motor and sensory neuropathies (SMA types II, III)
CIDP (SMA types II, III)
Neuromuscular Junction Disorders
Botulism (SMA type I)
Congenital myasthenic syndromes (SMA types I, II, III)
Lambert-Eaton myasthenic syndrome (SMA type III)
Autoimmune myasthenia gravis (SMA types II, III)
Myopathies
Congenital myopathies (SMA types I, II, III)
Congenital myotonic dystrophy (SMA type I)
Congenital muscular dystrophies (SMA types I, II)
Muscular dystrophies (DMD/BMD, LGMD) (SMA type III)
Inflammatory myopathies (SMA type III)
Channelopathies (SMA type III)
Metabolic Disorders
Mitochondrial myopathies (SMA types I, II, III)
Acid maltase/Pompe disease (SMA types I, II, III)
Other metabolic myopathies (SMA types I, II, III)
Hexosaminidase A deficiency (SMA types III, IV)
Acid ceramidase deficiency (SMA type III)
Other Disorders
Chromosomal abnormalities (SMA types I, II, III)
Prader-Willi syndrome (SMA types I, II)
Central nervous system abnormalities (SMA types I, II, III)
Hexosaminidase A deficiency (SMA types III, IV)

Abbreviations: ALS, amyotrophic lateral sclerosis; BMD, Becker muscular dystrophy; CIDP, chronic inflammatory polyneuropathy; DMD, Duchenne muscular dystrophy; LGMD, limb-girdle muscular dystrophy; SMA, spinal muscular atrophy; SMARD1, spinal muscular atrophy with respiratory distress 1.

GENETICS

The *SMN* Gene

About 95% to 98% of patients with SMA harbor deletions of the *SMN1* gene. The remainders are compound heterozygotes with an *SMN1* deletion in one allele and a small-scale intragenic mutation in the other *SMN1* allele or have undergone gene conversions from *SMN1* to *SMN2*. De novo mutations occur at a rate of about 2%, which is relatively high, and explained by the fact that this region of chromosome 5 is unstable, containing not only the inverted repeat of *SMN1* and *SMN2* but also other surrounding low copy number repeats. This leads to a high rate of unequal crossover and de novo mutations (especially paternally derived), which could explain the relatively high carrier frequency despite the mortality rate for the severe forms of the disease.

The number of copies of *SMN2* per chromosome 5 varies among normal individuals, and 10% to 15% of the population possess no copies of *SMN2*. Among patients with SMA, a clear inverse correlation has been established between *SMN2* copy number and phenotypic severity. Feldkotter et al in 2002 found that in their series, 80% of patients with type I SMA had one or two copies of *SMN2*, 82% of patients with type II had three copies of *SMN2*, and 96% of patients with type III had three or four *SMN2* copies (**Fig. 146.2**). However, this correlation is not so perfect as to predict the clinical severity in an individual patient based on *SMN2* copy number, especially with the intermediate forms of the disease where there is some overlap (patients with three or four copies of *SMN2* have been described with all three phenotypes). One reason for the overlap is that not all *SMN2* gene copies are equal; because of genetic modifiers, some copies probably produce less and some more than 10% functional protein. In general, though, it can be said that a patient with one or two copies of *SMN2* is highly likely to present with SMA type IA, IB, or IC. Current laboratory testing for the determination of *SMN2* copy number uses several techniques. The multiplex ligation-dependent probe amplification (MLPA) technique is felt to be the most accurate, especially when attempting to distinguish three from four from five copies.

FIGURE 146.2 Frequency of patients with spinal muscular atrophy (SMA) types I, II, and III and *SMN2* copy numbers. In spinal muscular atrophy type I, 80% of patients had one or two copies of *SMN2*, 82% of patients with type II had three copies of *SMN2*, and 96% of patients with type III carried three or four *SMN2* copies. (Modified with permission from Feldkotter MV, Schwarzer V, Wirth R, Wienker TF, Wirth B. Quantitative analyses of *SMN1* and *SMN2* based on real-time lightCycler PCR: fast and highly reliable carrier testing and prediction of severity of spinal muscular atrophy. *Am J Hum Genet*. 2002;70:358-368, Fig 3.)

Newborn Screening

The potential for newborn screening for SMA has been of great interest as the ideal time to initiate therapy would be prior to when the subclinical degeneration of motor neurons becomes symptomatic and there is the best opportunity to rescue the largest number of motor neurons. Swoboda et al performed a prospective study in prenatally diagnosed infants with type I SMA and found that, associated with the initial onset of symptoms or decline in function in these young infants, there was electrophysiologic evidence of precipitous denervation (assessed with serial measurements of compound motor action potential amplitude and motor unit number estimation), suggesting that motor neuron loss occurs very early. These observations reinforce the importance of newborn screening to identify genetically affected infants prior to the period of greatest motor neuron loss now that effective disease modifying treatments are available. The justification of adding newborn screening for the genetic identification of presymptomatic individuals with SMA has been demonstrated. SMA was added to the U.S. Department of Health and Human Services Recommended Uniform Screening Panel in 2018 and, as of late 2019, 20 states in the United States have implemented statewide or pilot newborn screening programs. Additional efforts are underway in Europe, especially Germany.

Regarding the issue of routine preconception and prenatal screening for SMA, the American College of Obstetricians and Gynecologists Committee on Genetics reaffirmed in 2019 their recommendation of preconception and prenatal screening for SMA in the general population.

PATHOBIOLOGY

SMA is characterized by spinal motor neuron loss and skeletal muscle atrophy. However, a precise understanding of how the cellular pathology of the disease evolves over its course continues to be handicapped by a paucity of suitable patient material. Our current appreciation of SMA pathophysiology stems largely from analyses of autopsy material, reflecting pathology at the end of the disease. Analyses of early disease pathology have relied mostly on murine models. Still, from the current studies, certain key findings emerge. These, almost invariably, include a profound loss of the large anterior horn cells of the spinal cord. Less frequently, motor neurons are found mispositioned. Surviving anterior horn motor neurons often appear swollen or chromatolytic, containing phosphorylated neurofilaments, ribosomes, and vesicles. In fewer instances, such pathology has also been observed in dorsal root neurons, cells comprising Clarke's column, and the thalamus of the brain. Intramuscular nerves in SMA patients sometimes appear beaded or are reported to undergo wallerian degeneration.

Considering the degeneration of the spinal motor neurons, an expected pathologic characteristic is neurogenic atrophy of the skeletal muscles. Muscle from severely (type I) affected patients typically consists of a sea of small, rounded, atrophic fibers within which are sometimes seen islands of one or more large hypertrophic cells. In some instances, the atrophic fibers also appear immature with centrally rather than peripherally located nuclei, giving the appearance of a myopathic condition or possibly that of early developmental arrest at the myotube stage.

Although SMA has historically been described as a disease characterized by motor neuron cell body loss, more recent data suggest the earliest pathologic effects of reduced SMN protein are observed distally, at the neuromuscular junctions. This early pathology that affects the pre- as well as postsynapse was first observed in mouse models of the disease and has now been confirmed in human samples as well (Fig. 146.3). Patients with SMA often describe significant fatigue, and repetitive nerve stimulation testing has demonstrated an increased incidence of a decremental response, adding electrophysiologic support to a myasthenic-like component to SMA.

MANAGEMENT

SMA is a unique "translational" disease because of the presence of the *SMN2* gene, which is a well-validated target for therapeutic interventions. Besides *SMN1* gene replacement using viral vectors, the effort on therapeutics has aimed at finding pharmaceutical compounds that can upregulate *SMN2* expression or affect other modifying genes to produce more functional SMN protein.

Agents That Upregulate *SMN2* Gene Expression and Promote Exon 7 Inclusion

Small Molecules

A class of drugs known as *histone deacetylase inhibitors* has been investigated extensively as potential therapeutic agents in SMA.

FIGURE 146.3 The neuromuscular junction defects in spinal muscular atrophy (SMA). The postsynaptic motor endplates are smaller and less complex compared to those of a control normal individual *(arrowheads)*. Tissue was obtained from autopsy and stained as a whole mount preparation with fluorescently labeled α-bungarotoxin. Scale bar: 30 μM. (Reprinted with permission from Monani UR, De Vivo DC. Neurodegeneration in spinal muscular atrophy: from disease phenotype and animal models to therapeutic strategies and beyond. *Future Neurol.* 2014;9[1]:49-65, Fig 2.)

Histones, which are core proteins in chromatin, play a role in epigenetic regulation of gene expression via their acetylation status. Several compounds that are histone deacetylase inhibitors, such as phenylbutyrate and valproic acid, have been shown to increase full-length *SMN2* transcript levels in cell lines from patients, usually by activating the human *SMN2* promoter, enhancing transcription, and correcting the splicing pattern; however, in clinical trials they failed to show efficacy.

Albuterol, a β-adrenergic agonist, was evaluated in a pilot open label study of 13 SMA type II and III patients due to its reported positive effect on muscle strength in healthy individuals. At 6 months, a significant improvement was noted in myometry, forced vital capacity, and dual-energy X-ray absorptiometry scores, but there was no significant change in Medical Research Council strength score. Another study of 23 SMA type II patients treated with salbutamol (a form of albuterol) for 12 months showed improved functional scores on the Hammersmith Functional Motor Scale (HFMS) after 6 and 12 months, but this was not a placebo-controlled study and must be interpreted with caution. Despite the lack of conclusive evidence, albuterol/salbutamol is sometimes prescribed to enhance endurance and diminish fatigue in SMA patients. Tremor may increase, and this can be problematic for SMA patients.

Other Approaches

Antisense Oligonucleotides

Antisense oligonucleotides (ASOs) have been developed that block an intronic splicing suppressor element, which in turn prevents skipping of exon 7. Periodic intracerebroventricular deliveries of ASOs in SMA mice models had been found to improve the motor phenotype. Based on the promise of preclinical studies and phase I/II clinical trials, randomized, double-blind, sham procedure-controlled phase III trials were developed by Ionis and Biogen. Pharmaceuticals were conducted to assess the safety, tolerability, and clinical efficacy of multiple doses of an ASO (ISIS-SMNRx), or nusinersen (Spinraza), which was delivered intrathecally into the subarachnoid space of patients with infantile or later onset SMA. The studies were successful LEVEL 1,[1] and nusinersen was approved broadly in 2016 by U.S. Food and Drug Administration, and later by European Medicines Agency (EMA) and other regulatory agencies as treatment for SMA. Long-term extension studies and postmarketing reports describe continued improvement for most patients treated with nusinersen; the safety profile remains favorable and the lumbar punctures generally well tolerated. There are challenges in delivering nusinersen intrathecally to patients who have undergone spinal fusion for correction of scoliosis or in patients with complex spines. Interventional radiologists have had success in most of these patients. The development of catheters and ports to deliver the drug is being explored currently.

Gene Therapy

Among other therapeutic targets, gene therapy has shown potential in animal models. Foust et al demonstrated that self-complementary adeno-associated virus 9 crossed the blood-brain barrier and infected approximately 60% of motor neurons when injected intravenously into neonatal mice. Remarkable therapeutic benefit resulted, with mice surviving 12 months or more with no evidence of muscle weakness. An *SMN1* gene replacement clinical trial (START) to treat SMA type I was conducted at Nationwide Children's Hospital, Columbus, Ohio, United States. The initial (START) trial with AVXS-101 showed positive results and has been followed by ongoing studies in the United States and Europe (STR1VE) LEVEL 1.[2] In 2019, the U.S. Food and Drug Administration approved AVXS-101 (onasemnogene) under the name Zolgensma for the treatment of SMA (symptomatic or presymptomatic) patients under age 2 years.

CARE OF THE PATIENT WITH SPINAL MUSCULAR ATROPHY

Patients with SMA and their families benefit greatly from a multidisciplinary approach to care. This approach involves members from neurology/neuromuscular medicine, orthopedics, physical and occupational therapy and rehabilitation medicine, pulmonology, nutrition, and gastroenterology. Genetic counseling remains important. For severely affected patients with type I SMA, early involvement of the pediatric advanced care or palliative care team can provide parents with support and assistance in making decisions that are consonant with their values and help to maximize their child's quality of life. In 2007 and 2018, Consensus Statements for Standard of Care in Spinal Muscular Atrophy were released by a multidisciplinary team regarding the current best recommendations for management of patients with SMA.

SUMMARY

Classic 5q-SMA is no longer a progressive neurodegenerative disease with a dismal prognosis. New treatments for symptomatic patients with SMA now provide some degree of rescue, with improved survival and motor function, but are not a cure. Early diagnosis and treatment after symptom onset offer the best opportunity for an optimal response to these drugs. Presymptomatic identification and treatment has resulted in normal motor development in many of these infants. The durability of these treatments, especially in growing children, remains to be determined. Combinatorial treatment may offer an enhanced response and will need to be addressed in future clinical investigations.

147 Muscular Dystrophies and Congenital Myopathies

James J. Dowling, Hernan D. Gonorazky, Dimah N. Saade, Michael W. Lawlor, and Darryl C. De Vivo

KEY POINTS

1. Muscular dystrophies and congenital myopathies are clinically defined by functional impairment of the skeletal muscle.
2. Key features include static weakness or dynamic changes including myalgias, cramping, myotonia, or rhabdomyolysis.
3. An elevated creatine kinase is found in most cases of muscular dystrophy.
4. Genetics provide a refined diagnosis beyond clinical features and muscle biopsy.
5. Clinical, histopathologic, and genetic features define the major subcategories of muscular dystrophies and congenital myopathies.
6. The age of onset of muscular dystrophies can vary widely and may also depend on genetic factors.
7. Treatment strategies are specific to each disorder, including supportive care in progressive disease.

INTRODUCTION

Muscular dystrophies and congenital myopathies encompass a spectrum of primary muscle disorders caused by mutations in genes that encode aspects of muscle structure and/or function. Onset is most typically in childhood, although there is tremendous variability (usually dictated by genetic subtype), and patients with genetic muscle disease may present at essentially any age. The definition of these conditions is evolving in the era of genomics. Whereas muscle biopsy findings were historically the driving factor for diagnosis, currently, genetics have primacy in most cases. In other words, most muscular dystrophies and congenital myopathies are defined by their underlying genetic cause.

DEFINITIONS

An operational definition of muscular dystrophy may include the following:

- Functional impairment of the skeletal muscle (either "static" resulting in weakness and the sequelae of that weakness or "dynamic" resulting in episodic symptoms such as myalgias, cramping, myotonia, or rhabdomyolysis)
- Dystrophic pattern on muscle biopsy (recent and older myofiber degeneration and regeneration, inflammation, and fibrofatty replacement) (Fig. 147.1)
- Elevated creatine kinase (CK) (typically > 800 U/L)
- Demonstration of pathogenic mutation(s) in a gene associated with muscular dystrophy

An operational definition of congenital/structural myopathy may include the following:

- Functional impairment of the skeletal muscle (typically non- or slowly progressive; static and/or dynamic as above)
- Suggestive findings on muscle biopsy, particularly including pathognomonic changes seen with subtypes such as nemaline myopathy (NM) (nemaline rods), core myopathy (either central cores or multiminicores), centronuclear myopathy (CNM) (central nuclei surrounded by haloes of oxidase positive organelles), and fiber-type disproportion (selective type I fiber hypotrophy, usually with type I fiber predominance) (Fig. 147.2)
- Normal to mildly elevated CK
- Demonstration of pathogenic mutation(s) in a gene association with myopathy

Muscular Dystrophy Classification

The classification of muscular dystrophies is based on clinical and genetic characteristics and fall into five broad categories: congenital muscular dystrophies (CMD), dystrophinopathies, limb-girdle muscular dystrophies (LGMD), scapuloperoneal myopathies (including Emery-Dreifuss muscular dystrophy [EDMD]), and other unique conditions (facioscapulohumeral muscular dystrophy or FSHD, myotonic dystrophy, and oculopharyngeal muscular dystrophy or OPMD) (Table 147.1).

Congenital Myopathy Classification

The classification of congenital myopathies has historically been dictated by muscle biopsy features. However, evolution in the field has mirrored the advances in genetics and genomics, and classification now represents a hybrid of clinical, biopsy, and genetic features. Congenital myopathies can be subdivided into the following categories based on their pathologic features: NM, core myopathy, CNM, and congenital fiber-type disproportion. In some cases, it is preferable to use terminology more reflective of the genetic changes to encompass a common genetic cause occurring across a range of morphologic patterns (as is seen in *RYR1*-related myopathies). Additional myopathies fitting more under a broader umbrella of "structural" myopathies include distal myopathies and myofibrillar myopathies.

Laboratory Diagnosis

Genetic testing via DNA extracted from blood is now the gold standard of laboratory diagnostics for muscular dystrophies and

FIGURE 147.1 Typical muscle biopsy findings in a muscular dystrophy. Hematoxylin and eosin staining displays evidence of recent myofiber degeneration and regeneration, including myonecrosis, myophagocytosis, inflammation, and basophilic fibers (indicative of recent regeneration), in addition to evidence of older myofiber degeneration and regeneration including internally nucleated fibers, endomysial fibrosis, and fatty infiltration (not shown in this image). Immunostaining for dystrophin (DYS2 antibody shown here) shows a complete loss of dystrophin in most or all fibers, possibly with a very small number of fibers that retain dystrophin expression. Expression of proteins that are not associated with the dystrophin glycoprotein complex (such as spectrin) will be retained at the sarcolemma, confirming that the tissue was sufficient in quality for the detection of dystrophin if it was present. Bar = 200 µm.

congenital myopathies, and a positive genetic test is considered the definitive diagnostic study. There are multiple technical approaches for genetic testing that include single gene tests (such as deletion/duplication analysis followed by Sanger sequencing for the *DMD* gene and Southern blot for the repeat expansion of *DMPK* 3′UTR in myotonic dystrophy type 1 [DM1]), multigene panels (encompassing sets of genes such as all LGMD genes or all congenital myopathy genes, performed on a "next-generation sequencing" platform), and whole exome sequencing. These approaches are all available on a commercial basis, with multiple providers offering various platforms. Of note, whole genome sequencing is not currently available on a clinical basis but is likely to be a front-line genetic testing strategy in the near future.

FIGURE 147.2 Muscle biopsy pathology in congenital myopathies. Representative images of muscle biopsies characteristic for central core disease (nicotinamide adenine dinucleotide stain shown), nemaline myopathy (Gomori trichrome stain shown), centronuclear myopathy (hematoxylin and eosin stain shown), and X-linked myotubular myopathy (hematoxylin and eosin stain shown). Central core disease, nemaline myopathy, and centronuclear myopathy are diagnosed by the presence of abnormal structures or distributions of organelles in the sarcoplasm. The differentiation of X-linked myotubular myopathy and centronuclear myopathies due to other genetic causes can often be made on the basis of very small fiber size and characteristically abnormal organelle distributions in X-linked myotubular myopathy. However, biopsies from the most severely affected patients with centronuclear myopathies related to other genes can display a similar appearance. Bar = 200 µm.

TABLE 147.1 Features of the Most Common Muscular Dystrophies

Disorder	Duchenne (DMD)	Facioscapulohumeral (FSHD)	Myotonic Dystrophy (DM1)	Emery Dreifuss	LGMD
MIM number	310200	158900	16090	EDMD1 310300; EDM2 181350; EDMD3 616516; EDMD4 612998; EDMD5 612999; EDMD6 300696; EDMD7 614302	Refer to Table 147.2
Incidence estimates	1 in 3,500 live male births	1 in 20,000 births	1 in 8,000 births	Variable depending on the genotype	Variable depending on the genotype
Mode of inheritance	X-linked recessive	Autosomal dominant	Autosomal dominant	EDMD1, EDMD6 X-linked; EDMD2, EDMD4, EDMD5, EDMD7 autosomal dominant, EDMD3 autosomal recessive	Please refer to Table 147.2
Gene defect	Deletion and duplication in 70% of the cases in dystrophin gene	FSHD1: reduced number of tandem repeats in D4Z4: 1-8 repeats (normal 10 to >100 repeats)	DM1: CTG expansion in protein kinase gene; 50 to >2,000 repeats (normal 5-37 repeats)	EDMD1 EMD; EDMD2 and EDMD3 *LMNA*; EDMD4 *SYNE1*; EDMD5 *SYNE2*; EDMD6 *FHL1*; EDMD7 *TMEM43*	Refer to Table 147.2
		FSHD2: mutations in chromatin modifier *SMCHD1* causing chromatin relaxation at D4Z4			
Expressivity	Complete	Variable	Variable	Variable	Variable
Age of onset	Childhood	Adolescence, rarely childhood	Broad range (infancy to adult life)	Variable, from neonatal to third decade	From toddler to adulthood
Weakness distribution					
Calf hypertrophy	Common	Never	Never	Never	Some, depending on the genotype
Rate of progression	Relatively rapid	Slow	Variable	Variable depending on the genotype	Variable depending on the genotype
Facial weakness	Rare and mild	Common	Common	None	None
Contractures	Common	Rare	Rare	Common	Common
Cardiac disease	typical onset in adolescence (cardiomyopathy)	None	Common (conduction defect AV block)	Common in EDMD1, EDMD2, EDMD3 (conduction defect, ventricular fibrillation)	Some, depending on the genotype
Other clinical features	Respiratory insufficiency, scoliosis, variable cognitive and neurobehavioral impairment	High-frequency hearing loss and retinal vasculopathy (rare)	Cataracts, endocrine dysfunction	Lipodistrophy in *LMNA*, scoliosis, rigid spine syndrome	Variable depending on the genotype

Abbreviations: DM1, myotonic dystrophy type 1; DMD, Duchenne muscular dystrophy; EDMD, Emery-Dreifuss muscular dystrophy; FSHD, facioscapulohumeral muscular dystrophy; LGMD, limb-girdle muscular dystrophy.

The specific genetic test to use for a patient is dictated by the clinical history, physical exam, and any available ancillary test results (such as creatine phosphokinase [CPK] levels, muscle biopsy findings, electromyography [EMG]/nerve conduction velocity results, and muscle and/or brain imaging). For example, first-line testing for a 3-year-old boy with frequent falls, a positive Gowers' sign, and large calves with a CPK >800 U/L would be focused exclusively on analysis of the *DMD* gene. Genetic evaluation for a 2-month-old female with neonatal hypotonia, diffuse weakness that includes prominent facial weakness, and respiratory difficulties and with a normal CPK would start with DM1 genetic testing and then (either concurrently or after a negative DM1 result) would utilize either a multigene panel that includes congenital muscle disease genes (congenital myopathies and congenital myasthenic syndromes) or whole exome sequencing. More details about genetic testing strategies are included in the individual disease subsections.

The use and application of nongenetic diagnostic tests is changing with the widespread availability of comprehensive genetic testing, and currently published diagnostic practice parameters in many cases require updating to reflect this evolving landscape. CPK levels are typically obtained on most/all patients with suspected muscle disease because they are inexpensive, minimally invasive to collect, and can provide important discrimination of subcategories of genetic muscle disease. EMG is no longer considered a first-line test, with the rare exception of the suspicion of a myotonic condition (noting that myotonia is not observed in myotonic dystrophy until after approximately age 6 y). EMG/nerve conduction velocity can be helpful when congenital myasthenic syndrome is in the differential diagnosis, although congenital myasthenic syndrome genes are well represented on relevant multigene panels.

If/when to perform a muscle biopsy is context dependent, and increasingly, muscle biopsy has become a second-line diagnostic test. This is because of the invasive nature of biopsy versus blood testing and the fact that genetic testing may provide a definitive diagnosis in the absence of a biopsy. Biopsy remains an excellent methodology for classification of patients with muscle disease, providing discrimination of dystrophy versus myopathy and enabling precise subtyping in many cases. For example, in individuals with CMD, muscle biopsy can delineate whether the cause is merosin deficiency, collagen 6 mutation, or dystroglycanopathy. Moving forward, biopsy will be most likely positioned as a test used to add validation to ambiguous genetic testing results (such as clarifying whether a novel variant of unknown significance in a gene is, in fact, pathogenic) and to aid in diagnostics when genetic testing does not establish a diagnosis. Muscle biopsy is also an ideal source material for advanced "omics" strategies such as RNA sequencing, which has been recently shown to be useful for identifying gene mutations in panel and/or exome negative cases.

Muscle ultrasound and magnetic resonance imaging (MRI) of skeletal muscle are increasingly used in the diagnostic evaluation. Muscle imaging can show the selective pattern of muscle involvement associated with some muscular dystrophies and congenital myopathies. For example, there is selective involvement of sartorius and adductor longus in selenoprotein N1 (*SEPN1*) myopathy with sparing of the gracilis. MRI offers good delineation between fatty infiltration and skeletal muscle and may guide the choice of the muscle to biopsy. It is somewhat limited by cost and by the fact that children younger than 5 years typically need sedation in order to tolerate the test. Muscle ultrasound is painless, is less expensive compared to MRI, and offers dynamic images. However, it requires a user familiar with muscle analysis. Overall, as with biopsy, muscle imaging is largely positioned as a second-line diagnostic modality useful for helping clarify uncertain genetic testing results and for providing ancillary data when genetic testing is not informative.

CONGENITAL MUSCULAR DYSTROPHIES

Definitions

CMD are generally defined by the following criteria: onset before 18 months of age, elevated CPK, and dystrophic features on muscle biopsy. In the genomics era, confirmatory gene mutation(s) in the setting of symptom onset in the preambulant aged child is sufficient for diagnosis. There are three major subtypes of CMD—merosin-deficient CMD (MDC1A, also called *LAMA2*-related CMD), COL6-related dystrophies (COL6-RDs), and dystroglycanopathy. They each account for approximately 30% of CMD cases, although there is variation between different regions and ethnic groups. The remaining 10% of CMD includes diagnoses such as rigid spine muscular dystrophy (which is discussed in the context of *SEPN1*-related congenital myopathies), Marinesco-Sjögren syndrome (an ultrarare condition featuring cataracts, brain abnormalities, and a mild muscle disease), and *LMNA*-related CMD (discussed in the context of EDMD) and *CHKB*-related CMD.

Epidemiology

The global incidence and prevalence of CMDs has not been rigorously established. A population study in Italy defined the prevalence as 0.563 per 100,000, whereas a population study in New Zealand established it as 0.64 per 100,000.

Diagnosis

CPK levels are typically elevated and can be as high as 10 times normal. Some individuals will have normal CPK, however, and a normal CPK cannot be used to exclude a CMD. Muscle biopsy usually shows classic features of a muscular dystrophy (degenerating/regenerating fibers, inflammation, fibrous, and fatty tissue replacement). Immunostaining of biopsies can be quite informative, as there are good antibodies to merosin/LAMA2, glycosylated dystroglycan, and to collagen 6. Diagnostic confirmation relies on identification of a causative gene mutation. Biallelic mutations in *LAMA2* are the only known cause of MDC1A. Mutations, either recessive or dominant, in 1 of the 3 COL6 genes (*COL6A1*, *COL6A2*, *COL6A3*) cause Ullrich congenital muscular dystrophy (UCMD). Dystroglycanopathies are caused by biallelic/recessive mutations in 1 of >20 genes. CMD genes are all included on commercially available multigene panels, and panel testing or whole exome sequencing is now typically pursued in infants with a consistent clinical picture prior to muscle biopsy. Important conditions to consider in the differential diagnosis of CMDs include congenital myopathies, congenital myasthenic syndromes, and spinal muscular atrophy.

Merosin-Deficient Congenital Muscular Dystrophy

MDC1A typically presents at or around the time of birth with hypotonia and diffuse extremity weakness. Infants with MDC1A also commonly have joint contractures, respiratory failure, and feeding difficulties. The disease is relatively nonprogressive throughout childhood, although there is a failure to meet most motor milestones, and individuals typically do not achieve the ability to stand or walk. Important comorbidities include scoliosis, which is usually severe, requiring of surgical correction and is often therapeutically recalcitrant, and respiratory difficulties, which often are progressive in the teen years and adulthood requiring noninvasive ventilation.

Historically, the diagnosis of MDC1A was made based on muscle biopsy, where the observation of absent merosin staining by immunohistochemistry establishes a diagnosis. Many patients are now diagnosed first by genetic testing, where biallelic *LAMA2* mutations provide a diagnosis in the appropriate clinical context. Care should be taken with interpretation of "negative" gene testing, as up to 30% of patients will not have an *LAMA2* coding sequence mutation of one or both alleles. Most likely, these represent cases with intronic *LAMA2* mutations or structural rearrangements of the *LAMA2*, as at present, *LAMA2* remains the only known cause of MDC1A. Of note, CPK levels in MDC1A patients are typically elevated, often 5 to 50 times of normal.

In addition, to muscle disease, individuals with MDC1A have abnormal brain MRI scans. The most typical pattern is diffuse white matter change seen on T2/fluid-attenuated inversion recovery that is similar in appearance to other leukoencephalopathies. The clinical consequences of these changes have been hard to precisely define, as most MDC1A patients do not have delays in cognitive development and have normal intelligence. There is an increased risk of epilepsy (up to 30%) and also infrequently observed malformations of cortical development. MDC1A patients also manifest demyelinating peripheral neuropathy. As with the brain MRI changes, the clinical symptoms associated with neuropathy in this patient subgroup are not well established.

LAMA2 encodes laminin-alpha2 (also known as merosin and laminin-211), a protein that forms part of heterotrimeric laminin-2/merosin protein in the extracellular matrix. Loss of LAMA2 results in failure to produce laminin-211, which in turn impairs the binding of myofibers (via integrin and dystroglycan receptors) to the basement membrane. This lost adhesion causes muscle membrane fragility and alters signaling pathways within the muscle cell. The sequelae of impaired signaling includes increased myofiber cell death; based on this concept, therapies aimed at blocking apoptosis have been successfully tested in preclinical models of MDC1A. One compound, a GAPDH inhibitor called Omigapil (NCT01805024), has been evaluated in a phase 1 clinical trial for MDC1A and UCMD (see below). Other therapeutic strategies include ones aiming at restoring adhesion to the basement membrane (e.g. synthetic laminin or mini agrin) and gene editing based therapies using CRISPR/Cas9.

COL6-Related Dystrophies

COL6-RDs are a clinically distinctive subtype of CMD. UCMD is the severe form of CL6-RD; it features the unusual combination of muscle weakness, joint hyperlaxity, and joint contractures. UCMD exists in a continuum with the allelic condition Bethlem myopathy, a later onset myopathy also characterized by joint laxity and contractures (Fig. 147.3). There are also some patients with features intermediate between UCMD and Bethlem myopathy. Other clinical features include keratosis pilaris, hyperextensible skin, and keloid scar formation. The disease is associated with progression including worsening joint contractures, the early development of scoliosis, and progressive respiratory decline (which often precedes loss of ambulation in Bethlem myopathy). Many UCMD patients fail to develop independent ambulation, whereas others lose motor skills over time.

FIGURE 147.3 Bethlem sign in COL6-related dystrophies. Depiction of the Bethlem sign or "prayer sign" in a patient with Bethlem myopathy. Long finger flexor contractures prevent full extension of the fingers when the palms are placed together with dorsiflexed wrists.

Diagnosis is usually suspected based on clinical phenotype. CPK levels can be normal or mild/moderately elevated. Mutations in one of three collagen 6 genes (*COL6A1*, *COL6A2*, and *COL6A3*) are the underlying cause of UCMD/Bethlem myopathy. Mutations can be dominant or recessive. Dominant mutations can be associated with mild or severe symptoms depending on how severely they disrupt the processing of the resulting collagen 6 protein. Recessive mutations, particularly ones that result in loss of expression of collagen 6, are most often seen in patients with a UCMD phenotype.

Collagen 6 is a heteropolymer formed from the three COL6 subunits (COL6A1/COL6A2/COL6A3). It is synthesized in fibro/adipogenic progenitors where it goes the first stages of oligomerization. Subsequent stages occur in the extracellular matrix, where the mature collagen 6 resides. Collagen 6 potentially interacts with several receptors on the muscle membrane. Loss of collagen 6 in the matrix impacts second messenger pathways within the muscle cell. As with MDC1A, increased apoptosis is proposed as one important pathomechanism, and drugs (such as omigapil) that block programmed cell death are under consideration as potential therapeutics. Due to the nature of the mutations that cause UCMD (particularly splice site and deep intronic alleles), UCMD is an excellent candidate disease for antisense oligonucleotide therapy (to alter/modify gene splicing), as supported by preclinical data including from patient cell lines.

Dystroglycanopathies

The dystroglycanopathies are a clinically and genetically heterogeneous subtype of CMD. The classic clinical phenotype is the Walker-Warburg syndrome, which features a constellation of features including ocular defects, cobblestone lissencephaly, intractable epilepsy, profound global developmental delay, and muscular dystrophy. It is one of the most severe neurogenetic disorders of infancy and often is associated with death in the first 18 months of life. However, dystroglycanopathies exist on a continuum, from Walker-Warburg syndrome to isolated LGMD without CNS involvement. Phenotypes along this spectrum include muscle-eye-brain disease, CMD with cognitive impairment, CMD without brain involvement, and LGMD. The clinical

picture is often dictated by the extent of central nervous system impairment and the severity of seizures.

There are >20 genes associated with dystroglycanopathy (DGopathy). The unifying element among these genes is that their gene products impact, in some way, the processing and glycosylation of dystroglycan. Dystroglycan is a transmembrane receptor that links the basement membrane (via binding to merosin) to the actin cytoskeleton (via association with dystrophin). Rare mutations in dystroglycan itself have been reported. The classic DGopathy genes are ones that encode Golgi apparatus glycosylation enzymes responsible for adding the unique O-mannose sugar modification to dystroglycan. Other DGopathy genes impact dystroglycan processing less directly, although result in similar phenotypes (ie, affecting brain structure and muscle integrity). The most commonly encountered DGopathy genes include *POMT1*, *POMT2*, *FKRP*, *FKTN*, and ISPD. A range of phenotypes can be seen with mutations in each of these, although there are some rough genotype-phenotype correlations. For example, *POMT1* and *POMT2* mutations more commonly cause Walker-Warburg syndrome, whereas fukutin-related protein (*FKRP*) mutations are most commonly associated with LGMD. Mutations in some of the genes are associated with unique clinical entities. For example, *GPPMB* mutations cause CMD with overlapping symptoms of congenital myasthenic syndrome.

While muscle biopsies are obtained in CMD patients at an ever-decreasing frequency, they often provide a critical clue for an underlying DGopathy. Specifically, they manifest abnormal immunostaining with an antibody specific for the glycosylated form of dystroglycan. This aberrant staining is not exclusive to DGopathies, but it enables successful subcategorization (particularly in the setting of CNS involvement) in many cases and has been used to subclassify patients as having DGopathy. With the classical DGopathy cases, CPK levels are usually highly elevated. In some of the more newly described genetic subtypes, CPK levels have been normal or only modestly elevated.

At present, therapy for DGopathies has been exclusively supportive in nature. DGopathies are excellent target diseases for gene replacement therapy as they (1) are typically caused by recessive loss of expression mutations and (2) are caused by small genes that can fit into most gene therapy vectors. Another strategy is to try and rescue the glycosylation defect on dystroglycan, and small molecular modulators have been identified in preclinical models. One open and important question is whether (and to what extent) individuals with severe presentations (such as Walker-Warburg syndrome) will respond to any disease-specific modulatory therapies.

Management

At present, care for all CMD subtypes is supportive in nature. There are no specific disease-modifying therapies or cures. Management is focused in several domains, including respiratory care, physio- and occupational therapy, and orthopedic management of contractures and scoliosis. Seizure management is important particularly in some subtypes of dystroglycanopathy and in some cases of MDC1A. Episodes of hypoglycemia, likely due to reduced muscle mass (and thus smaller gluconeogenic stores), have been reported, primarily in MDC1A patients, and require a high index of suspicion for their detection and treatment. A standard of care document, based primarily on best care practices, was released in 2010. Subsequently, subtype specific natural history studies have been completed, and these have enabled more precise clinical care.

DYSTROPHINOPATHIES

Definitions

Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) (MIM 310200, also referred to as *dystrophinopathies*) are allelic disorders caused by mutations in the dystrophin gene located at Xp21. Out-of-frame deletion or duplication mutations result in the absence of dystrophin protein leading to a severe clinical phenotype (Duchenne), whereas in-frame deletion or duplication mutations in which some dystrophin protein remains result in a milder clinical phenotype (Becker) (see **Table 147.1**). Point mutations can cause either DMD or BMD; nonsense mutations are most typically seen in DMD. There can be overlap in the clinical phenotype, and such cases are often classified as having an "intermediate" phenotype. DMD/BMD is considered X-linked recessive conditions, with males manifesting symptoms and females presenting as asymptomatic carriers. Female carriers can display symptoms and rarely have a severe childhood onset disease.

Epidemiology

The incidence of DMD is about 1 in 5,000 male births, with no clear geographic or ethnic variation. Approximately one-third of cases are caused by de novo mutations; the others are more clearly familial. A small percentage of cases are caused by gonadal mosaicism. Because the life span of patients with DMD is shortened, the prevalence is less—about 1 in 18,000 males. BMD is much less common, with an incidence estimated at 1:18,000 to 1:30,000 live male births, although the overall lifetime prevalence is 1:16,000 to 1:18,000 and is similar to DMD (due to the fact that BMD patient live significantly longer).

Duchenne and Becker Muscular Dystrophies

Duchenne Muscular Dystrophy

The condition may be presymptomatically detected in infancy if serum enzymes (such as alanine aminotransferase, aspartate transaminase, or CPK) are coincidentally measured. A positive family history may also alert an astute physician to the early recognition of motor delay. Symptom onset is classically described as occurring between ages 2 and 4 years, although this may reflect the challenge of evaluating weakness in young children. It is true, however, that symptoms are not present at birth. That said, young children with DMD score lower on scales that evaluate gross motor function. Walking is often delayed, and running is usually never normal; toe walking and waddling gait may also be evident. The condition is progressive, with worsening difficulties in walking, climbing stairs, and rising from chairs. An exaggerated lordosis is assumed to maintain balance. Patients tend to fall easily if jostled and have difficulty rising from the ground. In doing so, they use a characteristic maneuver called the *Gowers sign* (see **Fig. 147.2**). They roll over to kneel, push down on the ground with extended forearms to raise the rump and straighten the legs, then move the hands to the knees, and push up to a standing position. The Gowers sign is also seen in other conditions that include proximal limb and trunk weakness, such as most LGMD and spinal muscular atrophy (**Fig. 147.4**). Tendon reflexes (particularly in the lower extremities) may be diminished or absent, and calf hypertrophy is typically present.

As the disease progresses, the upper extremity becomes affected. Slight facial weakness may be seen, but speech, swallowing, and ocular movements are typically spared. Iliotibial contractures limit hip extension; heel cord contractures are partly responsible for toe walking. Loss of ambulation occurs between ages 9 and 12 years or later (12-14 y) when treated with glucocorticoids, after which patients become wheelchair dependent. Scoliosis may then become serious and may compromise limb and respiratory function. Elbow and knee contractures contribute to disability. Respiratory muscle weakness causes progressive decline in lung capacity beginning at about age 8 years. Nocturnal hypoventilation may occur and cause morning headaches and daytime fatigue if untreated. By about age 20 years, respiration is often compromised to the point that respiratory support is needed. Life expectancy in DMD has improved greatly in the last three decades, related to better coordinated medical and respiratory care combined with glucocorticoid therapy.

The heart is usually spared clinically until late in the disease when congestive heart failure and arrhythmias may develop. The electrocardiogram (ECG) is abnormal in most patients, with increased QRS amplitude in lead V_1 and deep, narrow Q waves in left precordial leads. Echocardiography shows progressively diminished contractility. Signs of cardiomyopathy may not be apparent because of the inability to exercise but may supervene in some cases. Early subclinical cardiac involvement is becoming increasingly recognized, as modalities such as cardiac MRI (which can detect more subtle changes than echocardiography) are more frequently employed in DMD patient care.

Constipation is common, but more severe gastrointestinal symptoms, such as intestinal hypomotility and acute gastric dilatation, are rare. Osteoporosis begins in the ambulatory years, is more severe in the legs, and may contribute to fractures. Intellectual impairment with predominantly verbal difficulties is seen in one-third of boys with DMD, and the average IQ is shifted approximately 1 standard deviation below normal. There is also an increased prevalence of neurobehavioral challenges in DMD boys, including attention deficit hyperactivity disorder and autism.

Anesthetic catastrophes may occur with hyperkalemia, extremely high CK levels (even more than 20 times the normal maximum), acidosis, cardiac failure, hyperthermia, and rigidity. The risk can be decreased by avoiding depolarizing muscle relaxants, particularly succinylcholine, and using care with volatile anesthetics. This vulnerability is distinct from malignant hyperthermia (MH).

Becker Muscular Dystrophy

This condition is defined by milder skeletal muscle weakness compared to DMD. Calf hypertrophy is present, weakness is greatest proximally, and serum CPK levels are high. EMG is myopathic and muscle biopsy reveals some staining of dystrophin. The two clinical features that distinguish it from DMD are differences in age at onset (typically after age 10 y) and rate of progression (still walking after age 16 y, often later). A differential exam feature compared with DMD is the absence of weakness of the neck flexors. Cognitive impairment is less common than in DMD. Cardiomyopathy usually develops later and may overshadow limb weakness. Cardiac complications contribute to 50% of BMD deaths compared with 20% with DMD, and some patients have severe cardiomyopathy with only mild muscle weakness. Another allelic disorder, X-linked dilated cardiomyopathy, demonstrates little to no skeletal muscle weakness. Some individuals with dystrophinopathy may only present dynamic symptoms, and DMD mutations are a leading cause of exertional rhabdomyolysis. In some instances, the only manifestation is elevated CPK levels (ie, hyperCKemia).

FIGURE 147.4 Gowers sign. Two panels showing a positive Gowers sign. In these pictures, the affected individual utilizes her hands to "walk up" her thighs from a squatting position to rise from the floor to standing. While a positive Gowers sign is most commonly associated with Duchenne muscular dystrophy, it may be present in any patient who has lower extremity proximal muscle weakness.

Intermediate Phenotype

Some patients show an intermediate phenotype that can be considered either severe BMD or mild DMD. Onset is shifted as compared to DMD, and such individuals remain ambulatory after age 12 years but use wheelchairs before age 16 years. They have preserved antigravity strength in the neck flexors longer than typical DMD patients.

Manifesting Carriers

DMD is an X-linked recessive condition. Female mutation carriers are usually asymptomatic, but "manifesting carriers" can have limb weakness, calf hypertrophy, cardiomyopathy, or high serum CPK levels. Cardiac screening is recommended in all carrier females.

Diagnosis

The diagnosis of Duchenne dystrophy is suggested in boys by typical clinical features (waddling gait, positive Gowers sign, calf/shoulder hypertrophy) in the setting of high CPK. Despite the recognizable features of DMD, there remains a diagnostic gap of approximately 2 years from average symptom onset to average age of diagnosis. Several international efforts have focused on increasing awareness in primary physicians of the presenting symptoms of DMD. Newborn screening (using serum CPK) is also feasible and may soon be available.

High CPK values are sometimes encountered in screening blood chemistry analysis done for other purposes; regardless of the clinical findings, and underlying dystrophinopathy should be considered. Similarly, screening liver function studies (alanine aminotransferase/aspartate transaminase), which are elevated in DMD, may be performed routinely when a child has an infection. If unexplained increased serum liver enzyme values are detected, serum CPK should then be assayed, and if elevated, a muscular dystrophy (of which DMD is most common) should be suspected, not a liver disease. Appropriate genetic testing should then be pursued (see as below and in subsequent sections). Of note, in DMD, serum CPK levels are highest in the presymptomatic years and then gradually decrease with age.

Increased CPK levels are also seen in girls and women who carry dystrophin mutations, in most/all forms of muscular dystrophy, in inflammatory myopathies such as dermatomyositis and anti-HMGCR necrotizing myopathy, in some patients with spinal muscular atrophy, and, for unknown reasons, in some otherwise asymptomatic individuals (idiopathic or asymptomatic hyperCKemia). Even before myopathic symptoms begin, high CPK values are seen in many muscular dystrophies, including DMD, the dysferlinopathies (LGMD2B or Miyoshi myopathy), and caveolin-3 mutations (LGMD1C). Clinical monitoring, combined with understanding of genotype-phenotype correlations, is required to determine the future impact and prognosis in cases of elevated CPK without overt clinical involvement.

Molecular Genetics

The dystrophin (*DMD*) gene is mutated in both Duchenne and Becker dystrophies, which are allelic diseases. Dystrophin encodes a cytoskeletal protein located at the plasma membrane. Brain and other organs contain slightly different isoforms. In muscle, dystrophin is associated with membrane glycoproteins that link the cytoskeleton with membrane proteins and then to laminin and the extracellular matrix (see Fig. 147.1). The protein plays an essential role in maintaining muscle fiber integrity. If dystrophin is absent, as in Duchenne dystrophy, or is abnormal, as in Becker dystrophy, the sarcolemma becomes unstable in contraction and relaxation, and the damage results in excessive calcium influx, thereby leading to muscle cell necrosis. If specific glycoproteins that associate with dystrophin are abnormal or missing, the same problems arise, as in some LGMDs (described later in the chapter).

Genetic testing, in the form of deletion/duplication analysis and direct DNA sequencing, is the primary method of establishing the diagnosis of DMD/BMD. Single or multiexon deletions or duplications account for about 65% of DMD and 85% of BMD patients. Patients with DMD typically have "frameshift" deletions/duplications that alter the DNA reading frame and consequently change amino acids downstream of the mutation, whereas individuals with BMD have milder "in-frame" rearrangements that maintain the sequence of amino acids flanking the mutation. Point mutations or small rearrangements account for the remainder and can be detected by gene sequencing. Carriers can be similarly identified, and the test can also be used for prenatal diagnosis. Genetic counseling is critical both before and after testing, and the diagnosis of DMD/BMD has important implications for family planning and potentially for those related to the affected individual.

The initial evaluation of a boy suspected to have dystrophinopathy includes a serum CPK followed by genetic screening for *DMD* mutations performed on peripheral blood leukocytes. Mutations that interfere with the expression of dystrophin cause DMD and those that lead to abnormal quality or quantity of dystrophin cause BMD. Muscle biopsy is typically only pursued in cases where the diagnosis is highly suspected but the genetic testing is unrevealing, in atypically presenting cases, and in the setting of variants of unknown significance in the *DMD* gene. Immunocytochemistry for dystrophin and Western blot for quantitative dystrophin analysis can confirm and refine the diagnosis in these questionable cases. In DMD, dystrophin staining is absent by both immunocytochemistry and Western blot. In BMD, immunocytochemistry may show an interrupted pattern of staining on the surface membrane or negative staining with a subset of antidystrophin antibodies (with preservation of dystrophin signal using other antibodies), and the Western blot shows decreased dystrophin levels or abnormal protein size. Of note, approximately 5% of cases are due to deep intronic mutations, which can be uncovered through analysis of RNA from muscle biopsies.

Management

Standard of care guidelines for Duchenne muscular dystrophy, based on both clinical trial evidence and expert opinion, are published and widely available LEVEL 1.[1] These include recommendations for multidisciplinary team composition, appropriate respiratory, orthopedic and cardiac care, and specific pharmacologic interventions. Adherence to these care practices has led to improvements in the clinical course of DMD and an increase in overall survival of 5 to 10 years.

Oral corticosteroids are effective, standard of care therapy for DMD. Prednisone (0.75 mg/kg/d) or deflazacort (0.9-1.2 mg/kg/d) can be used. Prednisone therapy improved function and strength in placebo-controlled trials, but the side effects of chronic administration—in particular, weight gain, growth retardation, osteoporosis, cataracts, and behavioral changes—can limit their long-term use. If not prohibited by side effects, prednisone is usually offered to ambulatory patients older than 5 years of age and should be continued until side effects outweigh benefits, which typically occurs after ambulation is lost. Data on the use of prednisone before

age 5 years is lacking, and the extent of continued benefit after a child becomes wheelchair dependent not fully known. Of note, several alternative dosing strategies are being considered (such as alternate day or weekend only high dose). These strategies offer fewer side effects and seem to have equivalent benefits to daily dosing in the short term. However, further study is needed to know if they provide the same long-term impact. Also, new analogs designed to have the positive effects of steroids without the side effects are currently in clinical testing and may ultimately replace glucocorticoid treatment.

Although current therapy has improved the lives of boys and men with DMD, new and additional therapies are still greatly needed, as life expectancy still only reaches the early 30s. Several exciting therapeutic approaches are currently being investigated. These include antisense oligonucleotide-based exon skipping, a strategy designed to restore reading frame in patients with suitable deletions by removing additional exons. One such drug, eteplirsen, has been granted provisional U.S. Food and Drug Administration approval, but confirmatory phase III data is still lacking. Another strategy is gene replacement therapy or gene therapy. Because dystrophin is too large to fit into conventional viral vectors (such as AAV8/9), micro- or minidystrophins have been designed and tested. Currently, at least four different microdystrophin-based gene therapies are being evaluated in clinical trials. A third gene-based approach is premature stop codon "read through," a strategy whereby a drug prevents the stopping of translation at premature nonsense codons and limits nonsense mediated decay of the RNA. Ataluren is a "read-through" drug that has provisional U.S. Food and Drug Administration approval for patients with DMD and nonsense mutations. Its true efficacy is still under investigation. One final exciting technology is CRISPR/Cas9 gene editing, which offers the potential of correcting mutations at the genomic DNA level. Based on suggestive preclinical data, the first clinical trials of CRISPR for DMD are in the planning stages.

Supportive management in DMD is aimed at maintaining function and independence, avoiding complications, and improving quality of life. *Orthopedic and rehabilitation measures* include stretching exercises and ankle-foot orthoses during sleep to prevent contractures. Later, standing and walking can be maintained with ankle-foot orthoses or knee-ankle-foot orthoses combined with standing devices or walkers. Surgical release of contractures is only occasionally used for functional reasons, such as maintaining standing or ambulation. During the wheelchair years, surgical scoliosis stabilization can help maintain a comfortable sitting position and may reduce the risk of atelectasis and pneumonia.

Pulmonary function should be monitored regularly in patients with respiratory symptoms and in those who are nonambulatory to detect declines in respiratory muscle strength or ability to cough. Reduced cough strength increases the risk of atelectasis and respiratory infections. Therefore, chest physical therapy and mechanical insufflators/exsufflators are useful. When symptoms of sleep-disordered breathing are suspected, overnight in-home oximetry or laboratory-based sleep studies can confirm nocturnal hypoventilation. Noninvasive nighttime mechanical ventilation should then be considered. Later in the disease when respiratory muscle weakness progresses, continuous noninvasive ventilation is often needed, and sometimes the difficult decision whether to do a tracheostomy arises.

Cardiac function should be assessed prior to any major surgery in those with respiratory insufficiency or cardiac symptoms and, at least annually beginning at approximately 8 years of age. Current screening involves ECG and echocardiogram; cardiac MRI is increasingly being used, as it detects changes before they are apparent on echo. Perindopril (2-4 mg/d) has been shown to improve cardiac function in DMD and likely slows the progression of cardiac disease. Interventions including implantable cardioverter defibrillator placement and cardiac transplantation has been performed in select BMD patients. *Other measures* include precautions with general anesthesia, influenza and pneumococcal vaccinations, weight control, maintenance of bone health, neuropsychological evaluation to guide in educational issues, and social support to aid emotionally and financially. Genetic counseling for families is crucial.

SCAPULOPERONEAL MYOPATHIES

Emery-Dreifuss Muscular Dystrophy

EDMD is a clinically and genetically heterogeneous muscular dystrophy subtype united by a triad of signs/symptoms (Fig. 147.5):

1. A characteristic humeroperoneal distribution of weakness. That is, the biceps and triceps are affected rather than shoulder girdle muscles, and distal muscles are affected more than proximal muscles in the legs. The limb weakness may be mild or severe.
2. The presence of contractures that are disproportionately severe and are evident before much weakness is noted. The contractures affect the elbows, knees, ankles, fingers, and spine. A rigid spine often develops, and neck flexion can be limited.
3. Important cardiac disease: Heart block, atrial paralysis, and atrial fibrillation are found in 95% of patients by age 30 years and lead to placement of a pacemaker. Dilated cardiomyopathy occurs in about 35% of all cases.

FIGURE 147.5 Clinical features of Emery-Dreifuss muscular dystrophy (EDMD). Individual with EDMD due to dominant mutation in FHL1 gene with two of the classical aspects of the triad of signs/symptoms seen in EDMD: wasting of the humeral musculature and elbow flexion contractures.

EDMD has been associated with mutations in six genes, with variants in *LMNA* and *EMD* accounting for the vast majority of cases. Dominant mutations in the lamin A/C gene (*LMNA*) are the most common cause and present a spectrum of phenotypes from congenital onset muscular dystrophy, to the EDMD phenotype (MIM 181350), to a limb girdle presentation. Next most common is the X-linked form (MIM 310300) caused by mutations in emerin (*EMD*). Of note, *LMNA*-related EDMD tends to present earlier and with more severe symptoms than disease due to *EMD* mutations. Other causes include mutations in the X-linked gene *FHL1* encoding four-and-a-half LIM protein 1, and rarely autosomal dominant mutations in *SYNE1* (MIM 612998), *SYNE2* (MIM 612999), and *TMEM43* (MIM 614302). The overall prevalence is approximately 1:100,000. A proportion of cases remain genetically unresolved.

Symptoms of EDMD often start before age 5 years with difficulty walking. Examination typically shows symmetric contractures and weakness without pseudohypertrophy. Tendon reflexes are hypoactive or absent, and there may be mild facial weakness. Head drop may be present, particularly with early-onset forms of *LMNA* mutation. Serum CK activity can be mildly elevated to levels less than 10 times normal. The diagnosis is usually confirmed by DNA testing. Absence of emerin can be demonstrated by immunocytochemical study of a muscle biopsy. Emerin staining is absent not only in muscle nuclei but also in circulating white blood cells and skin. As a result, skin biopsy, leukocytes, or inner cheek swabs for exfoliated mucosal cells can be examined diagnostically instead of muscle biopsy. However, given that other EDMD subtypes (including *LMNA*) cannot be reliably discerned by immunostaining, DNA or gene product analysis is preferred to establish accurate diagnosis. Cardiac surveillance (including 24-h ECG and echocardiography) is crucial.

EDMD must be distinguished from other conditions. The rigid spine syndrome includes vertebral and limb contractures but not cardiomyopathy or muscle wasting. Because the cardiac abnormality may not be evident in childhood, some patients with a rigid spine might be expected to have EDMD. As discussed in the CMD section, collagen 6–related disorders (Bethlem myopathy/Ullrich CMD-MIM 158810/254090).

Management is symptomatic and may include physical therapy and surgical tendon release for contractures. Pacemaker/cardioverter-defibrillator (implantable cardioverter defibrillator) implantation and treatment of cardiomyopathy is often crucial. Female carriers are at risk for arrhythmias and should have regular cardiac evaluations.

LMNA-Related Myopathies

Mutations in *LMNA* represent the commonest cause of EDMD but are also seen in a spectrum of muscle diseases including CMD and LGMD. There are also rare patients reported with Charcot-Marie-Tooth and mutations in *LMNA*, and a distinctive premature aging condition (progeria) associated with specific mutations in the C-terminus of the gene. Patients with myopathic presentations have a range of severe manifestations. All are unified by the presence of early-onset and progressive contractures. The congenital form of the disease is particularly aggressive, with progressive neck flexors contractures, scoliosis, and respiratory failure, leading to the need for early ventilatory support and scoliosis surgery. Such patients often do not survive into adulthood. Note that all myopathic patients with *LMNA* mutations have elevated CPK values. Muscle biopsy findings are nonspecific and may show focal areas of inflammation and necrosis, and there is no antibody currently available that allows the reliable demonstration of LMNA loss. Diagnosis therefore rests on identification of causative mutations in the appropriate clinical setting.

LMNA encodes the nuclear envelope intermediate filament protein lamin A/C. Taken with the fact that several of the other causes of EDMD are associated with nuclear envelope proteins, the disorder in general is considered to have its root pathology with the abnormal structure and function of the nuclear membrane. While pathomechanisms are still being worked out, the predominant theory is that this disturbance of the nuclear envelope leads to mechanical instability of the myofiber and to alterations in gene expression.

Presently, management for *LMNA*-related myopathies focuses on anticipatory respiratory care, physiotherapy and surgical intervention for contractures and scoliosis, and treatment for cardiac arrhythmias. Arrhythmias are a leading cause of death in this disorder and must be proactively monitored upon clinical suspicion of the disease. Implantable defibrillators have been shown to reduce severity of arrhythmias and to improve survival.

At present, there are no experimental therapies in clinical trial for *LMNA* muscle disease. Given the inflammation seen on muscle biopsy, steroid therapy has been considered, and anecdotal cases support its further study. A systematic investigation of this is underway. Other considerations include gene therapy using a trans-splicing approach and allele-specific silencing using antisense oligonucleotides targeted to specific mutations, although this strategy requires careful consideration as haploinsufficiency of *LMNA* may lead to cardiomyopathy.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

Definition

FSHD (MIM 158900) is defined by characteristic clinical features that include facial weakness (affecting primarily eyelid closure and lower facial movement), weakness of the scapular stabilizers (leading to the characteristic appearance of scapular winging) (Fig. 147.6), and prominent involvement of humeral muscles

FIGURE 147.6 Asymmetric scapular winging in facioscapulohumeral muscular dystrophy. Asymmetric scapular winging, a classical feature of facioscapulohumeral muscular dystrophy, may also be observed in other forms of muscular dystrophy. It results from weakness of the scapular stabilizing muscles.

in the upper extremity, abdominal and truncal muscles, and distal muscles in the lower extremity. Ultimately, the condition is defined by the presence of a positive genetic test. There are two forms of FSHD, FSHD1 and FSHD2, that share similar clinical symptoms but differ based on underlying genetic change.

Molecular Genetics

The disease is autosomal dominant with nearly complete penetrance. Almost all FSHD patients have deletion/contraction of a 3.3-kilobase repeat element, termed *D4Z4*, on the subtelomeric end of chromosome 4q35. Normal individuals have 11 to 150 repeats; FSHD1 patients usually have fewer than 11. The deletion results in inappropriate expression of the double homeobox–containing gene *DUX4* in muscle cells. Of note, the deletion must occur on a permissive 4q allele (4qA) in order to cause disease. Also, there is correlation between repeat number and clinical severity, with fewer repeats equating to earlier onset and increased severity. About 5% of FSHD patients have chromatin relaxation at D4Z4 without D4Z4 contraction resulting from dominant mutation in the chromatin modifier gene *SMCHD1*. This rare form is referred to as *FSHD2*.

Clinical Manifestations

The following features are characteristics of FSHD:

1. Facial weakness is evident not only by limitation of lip movements but also in the slightly everted lips and wide palpebral fissures. Patients may state that they have never been able to whistle or blow up a balloon. Some are said by relatives to sleep with eyes open.
2. Scapular winging is prominent. Protrusion of the scapula is more evident when the patient tries to push against a wall with elbows extended and hands at shoulder level. The winging becomes more evident when the patient tries to raise the arms laterally. The patient cannot raise the arms to shoulder level even though there is no weakness of the deltoids on manual testing. This limitation is caused by inadequate fixation of the scapula to the chest wall.
3. The shoulder girdle has a characteristic appearance. Viewed from the front, the clavicles seem to sag and the tips of the scapulae project above the supraclavicular fossa. This abnormality becomes more marked when the subject tries to raise the arms laterally to shoulder level. Smallness of the pectoral muscles affects the anterior axillary fold, which is ordinarily diagonal but assumes a vertical position. Abdominal muscle weakness may cause abdominal protrusion and exaggerated lumbar lordosis. The lower abdominal muscles are weaker than the upper causing a positive "Beevor" sign with the navel moving toward the head upon neck flexion in a supine position. The limb muscle weakness is often asymmetric. It is important to remark that weakness and atrophy in most patients is asymmetric if one compares one hemibody with the other. This feature is not commonly found with other muscular dystrophies making it a key feature in order to arrive to a diagnosis.
4. Leg weakness may affect proximal muscles or, more often, the tibialis anterior and peroneals, resulting in foot drop.

Within a single family, the condition may vary markedly. Progression is slow, however, and the condition may not shorten longevity. About 20% of patients eventually use a wheelchair. Respiratory insufficiency is rare. Men may be more severely affected than women. The disease may present in the first 2 years of life in individuals with large deletions (congenital FSHD).

Associated Disorders

Occasion additional features include mild sensorineural hearing loss, vascular retinopathy, Coats disease (exudative telangiectasia of the retina), and, rarely, intellectual disability in congenital onset cases. Cardiac involvement is rare in FSHD. On the other hand, pain is common, with frequent sites including, in descending order, lower back, lower limbs, shoulders, and neck.

Differential Diagnosis

The differential diagnosis includes myogenic and neurogenic scapuloperoneal syndromes and some forms of LGMD (such as LGMDR1), especially when facial weakness is absent. Additionally, EDMD is sometimes confused with FSHD, but the essential clinical features are different. The increasing availability of genetic testing for FSHD, LGMD, and EDMD typically provides diagnostic clarity in these settings. Infantile onset of FSHD is rare, but facial weakness may be severe enough to simulate the Möbius syndrome of congenital facial diplegia.

Laboratory Studies

The diagnosis is established by leukocyte DNA testing for a contraction of the subtelomeric repeat array on 4q35. Presymptomatic diagnosis is possible in families with more than one affected member, but testing should be done only with appropriate counseling. EMG and muscle biopsy, by definition, should show a myopathic pattern. Muscle biopsy changes are usually mild and nonspecific. Inflammatory cells are found in some patients, raising the question of polymyositis, but immunosuppressive therapy is not effective. Rarely, patients with typical manifestations do not have a causative mutation for FSHD1/FSHD2, which may imply additional locus heterogeneity or potentially limits of sensitivity of current tests for the known mutation loci.

Management

Currently, there are no disease-modifying treatments for FSHD. Scapular weakness becomes progressively disabling, and some interventions are commonly tried despite lack of compelling evidence. These include taping and vests for scapular stabilization, and wiring of the scapula to the chest wall to facilitate use of the arms. Additional supportive treatments include physical therapy, analgesics for joint pain, and ankle-foot orthosis for foot drop. Albuterol, a β_2-agonist sympathomimetic drug, was evaluated in a placebo-controlled phase 3 clinical trial. The primary end point, a difference in global strength, was not reached, but the drug did improve two secondary end points: grip strength and muscle mass.

Therapeutic development is focused primarily on strategies to reduce DUX4 expression or DUX4-related toxicity. A small molecule p38 inhibitor is currently being evaluated in clinical trial, having been shown to reduce DUX4 expression in patient cells. Gene-based knockdown strategies, either using antisense oligonucleotides to DUX4 or viral-based gene therapy, are attractive approaches that have been tested in preclinical models and are likely to soon enter clinical trial.

MYOTONIC MUSCULAR DYSTROPHY AND PROXIMAL MYOTONIC MYOPATHY

Definitions

Myotonic dystrophy (DM1; MIM 160900) is an autosomal dominant, multisystem disease with unique symptomatology that includes muscular dystrophy, myotonia, cardiomyopathy, cataracts, and endocrinopathies. *Proximal myotonic myopathy* (PROMM, DM2; MIM 602668) shares many characteristics with DM1 but differs based on age of onset and underlying genetic cause.

Epidemiology

DM1 is typically not life limiting (with some exceptions), and penetrance is almost 100%. Because of this, DM1 is a disease of high prevalence, about 5 per 100,000 throughout the world, and is likely the most common adult form of muscular dystrophy. The incidence is about 13.5 per 100,000 live births. The disease is found throughout the world, although there are areas with founder mutations and very high prevalence, such as the Charlevoix-Saguenay region of Northeastern Quebec.

FIGURE 147.7 The myopathic facial appearance typical of myotonic dystrophy. Individual with congenital myotonic dystrophy (>1,000 CTG repeats in DMPK 3′UTR). Note the classic features of bitemporal wasting, bilateral ptosis, and lower facial weakness (resulting in the C-shaped appearance of the mouth).

Diagnosis

Clinical Features

The clinical features of DM1 are characteristic and the diagnosis is often evident by clinical inspection. Early foot drop may lead to confusion with Charcot-Marie-Tooth disease, but EMG patterns distinguish the two. The congenital form (congenital myotonic dystrophy [cDM1]) may resemble a congenital muscle disease, particularly X-linked myotubular myopathy (XLMTM) (which shares many clinical features with cDM1 and may manifest similar changes on muscle biopsy), or instead a syndrome with global developmental delay.

The myopathy of DM1 is distinctive in distribution and appearance. Unlike most other forms of muscular dystrophy, it affects facial musculature in addition to the extremities. Ptosis is common, and dysarthria and dysphagia may occur. The temporal, lower facial, and sternocleidomastoid muscles are weak and atrophic, resulting in a distinct facial gestalt (Fig. 147.7). In men, frontal baldness contributes to this impression. Limb weakness is most pronounced distally and affects the hands and feet equally. Distal leg weakness may cause a foot drop or steppage gait. The rate of progression is slow, and longevity may not be affected, but variation is evident; some people are almost asymptomatic, some experience progressive disability, and some are born with a more severe subtype called cDM1.

Electrodiagnostic Features

Myotonia is a core feature of the disease. Clinical myotonia is a phenomenon of impaired relaxation. It is most evident in the hands as failure of hand opening. It may impair skilled movements and complicate actions such as shaking hands or turning a doorknob. As a sign on examination, the slow relaxation can be elicited by tapping the thenar eminence or, in the forearm, the bellies of the extensors of the fingers. Myotonia can also be evoked by asking the patient to grasp forcefully and then relax, which an unaffected person can do rapidly. Of note, the myotonic phenomenon is due to a secondary involvement of the *CLC1* gene encoding the chlorine channel.

Interestingly, myotonia typically is not seen until age 7 years at the earliest; thus, EMG is not useful before this age. Electrical myotonia is a distinctive pattern of waxing and waning high-frequency discharges observed on EMG. Myotonic discharges are seen in other disorders as well, such as "nondystrophic myotonias," which are described in other chapters: hyperkalemic periodic paralysis and paramyotonia congenita in Chapter 97 and myotonia congenita and the Schwartz-Jampel syndrome in Chapter 98. "Pseudomyotonia," or impaired relaxation without true myotonic discharges, is seen in the Isaac syndrome or neuromyotonia (see Chapter 98). Myotonic-like discharges, but not clinical myotonia, are seen in patients with acid maltase deficiency. Inclusion body myopathy with both Paget disease and frontotemporal dementia can be associated with electrical-myotonia. However, none of these other myotonic syndromes has the characteristic myopathy and multisystem involvement of DM1 and therefore rarely cause diagnostic confusion. *Muscle biopsy* may show a dystrophic pattern with an increased percentage of internalized nuclei. Serum CK level may be normal or slightly increased.

Other Clinical Features

Cataracts are almost universal but take years to appear. Early findings include characteristic iridescent opacities and posterior opacities called "Christmas tree cataracts." Cataracts are related to the decreased expression in the gene *SIX5*.

Endocrinopathy is most readily seen in men. Frontal baldness is almost universal, and hypogonadism (testicular atrophy, tubular degeneration, reduce testosterone, and oligospermia) is common; fertility in males, however, is not clearly diminished.

In females, menstrual irregularities and ovarian failure are observed but only rarely; difficulties during pregnancy may occur due to uterine muscle hypercontraction. Diabetes mellitus and insulin resistance may be more common than in the general population, and therefore, annual measurements of glucose and glycosylated hemoglobin should be considered. Hypothyroidism is rare but should be considered so that untreated hypothyroidism does not contribute to muscle weakness.

Cardiac involvement is manifested as conduction disturbances, including atrial fibrillation and ventricular tachyarrhythmias, in more than half of the adult patients with DM1. The most frequent finding is AV conduction block (between 28% and 58%). Fatal arrhythmias are an important problem. It is therefore recommended that patients have cardiac screening at diagnosis and annually thereafter. The workup should include 12-lead ECG and, if suspicion of arrhythmia, should also include 24-hour Holter monitoring and echocardiogram. Permanent pacing is recommended if/when abnormal rhythms are detected. Cardiac involvement is due to the involvement of several genes including the mis-splicing of *SCN5A*.

Involvement of the gastrointestinal tract is frequent. Most patients will have difficulties swallowing and may experience dysphagia, dyspepsia, and reflux. Diarrhea with abdominal cramping is also a common complaint. Other complications are pseudoobstruction or megacolon. Although the abnormalities on the skeletal muscle are well-defined, histologic evidence of smooth muscle abnormalities are confounding. Thus, the pathophysiologic explanation for the gastrointestinal manifestation remains evasive.

Cognitive impairment is common in cDM1, and intellectual disability is rare in patients with later onset. However, mild cognitive and neuropsychiatric impairment may be evident. cDM1 usually presents with a global cognitive involvement, whereas classic DM1 only involves executive function. Juvenile forms of DM1 present with a higher involvement of all memory domains compared with the adult forms. There is also documented a progressive decline of the frontal and temporal functions in adult forms of DM1.

Excessive daytime somnolence is most frequently attributed to nocturnal hypoventilation, but there are other explanations as well. Several studies have described a central rapid eye movement sleep dysregulation that may contribute to the somnolence frequently reported in this population. The incidence of diurnal somnolence, as measured through the Daytime Sleepiness Scale, was significantly higher in DM1 patients (50%) than in DM2 patients (27%). These symptoms may be helped by treatment with modafinil or methylphenidate. *Respiratory difficulties* may occur due to diaphragmatic and intercostal muscle weakness as well as impaired respiratory drive.

Genetics

Ultimately, DM1 is a genetic diagnosis. It is caused by expansion of a CTG repeat in the 3′UTR of one allele of the *DMPK* gene located on 19q13.2. Unaffected people have 5 to 30 CTG repeats; affected individuals have more than 50. Infants with cDM1 have more than 800 repeats and typically have >2,000. It is an autosomal dominant disease, and each successive generation has more repeats and is more severely impacted. In general, the larger the repeat, the younger the age at onset and the more severe the syndrome, which is a phenomenon referred to as *anticipation*. Of note, there is rapid anticipation of repeats from maternal alleles, and the cDM1 form only results when the mother has a pathogenic repeat. Genetic counseling is critical in this disorder and should be provided both before testing is initiated and upon return of the results, as there are almost always important implications for additional family members (including parents and their siblings).

Myotonia Variants

Congenital Myotonic Dystrophy

About 5% of children born to a person with DM1 have symptoms at birth, a condition termed *congenital myotonic dystrophy*. It affects children of either sex who are born to a woman with the usual adult form of the disease, which is often so mild that the woman may be asymptomatic at the time of diagnosis in the child. cDM1 infants have difficulty feeding and breathing in the newborn period, develop slowly, present with global cognitive delay, and show developmental anomalies of the face and jaws as well as severe limb weakness and clubfeet. Importantly, symptoms improve after the first year of life: Nearly every child with cDM1 eventually walks. The disease process tends to go through four phases: severe neonatal symptoms, progressive improvements in developmental milestones, plateau of progress and of symptomatology, and lastly progression as typically seen in patients with classic disease.

Proximal Myotonic Myopathy

When the mutation causing DM1 was discovered in 1992, it became evident that some patients did not carry the mutation. Their symptoms and signs are similar to those of DM1 in many respects, including autosomal dominant myopathy, myotonia, cataracts, and weakness of the sternocleidomastoids. The distribution of limb weakness is different: DM1 is primarily a distal myopathy, whereas DM2 presents weakness of pelvic girdle muscles. Other differences are less conspicuous. For instance, myotonia is more difficult to elicit, symptoms are less severe, and there may be calf hypertrophy. Congenital and pediatric presentations have not been reported in DM2 families, and anticipation is not prominently observed. Most important, the syndrome does not map to chromosome 19 but maps to chromosome 3q and is caused by a CCTG expansion in the *CNBP* gene.

Management

Myotonia can be ameliorated with mexiletine (150-1,000 mg/d, class 1 evidence), phenytoin sodium (Dilantin) (300-400 mg/d), or other anticonvulsant drugs. Rehabilitation measures are helpful for muscle function and in assisting the patient in the activities of daily living. Orthoses help with foot drop. Ocular and cardiac symptoms are treated as in any patient. An ECG should be recorded annually for adults, and slit lamp examination is also carried out periodically. Glucose metabolism, thyroid function, and, in symptomatic males, testosterone levels should be periodically monitored and when abnormal, treated. Fatigue is common and often responds to pharmacologic treatment such as modafinil (200-400 mg/d). Pain is a frequent symptom and should be managed with pharmacologic and other approaches. General anesthesia should be avoided if possible because of increased postoperative pulmonary complications. In cDM1, respiratory support and feeding tubes are often needed in infancy, and feeding support may be required at all phases of the disease. Early intervention with physical, occupational, and speech therapy and special education are indicated to address the problems associated with global developmental delay. Families should be educated about the nature of the disease, inheritance, and the availability of DNA diagnosis for adults and for prenatal testing.

The primary pathomechanism underlying the disease is alteration of RNA splicing as a result of the toxic RNA produced from the *DMPK* locus. The expanded repeat in the 3′UTR forms a hairpin that then sequesters factors (muscle-blind proteins) that are critical for regulating splicing. The result is mis-splicing of hundreds of genes in the affected tissues, resulting in the stereotyped multiorgan involvement of the disorder. Several of these mis-splicing events are tied to specific phenotypes, such as the mis-splicing of *CLC1* that results in myotonia. The main experimental therapeutic strategies are aimed at either reducing the toxic RNA species or else replenishing muscleblind proteins. For example, an antisense oligonucleotide-based approach that promotes degradation of the repeating containing DMPK is currently under development.

LIMB-GIRDLE MUSCULAR DYSTROPHY

Definition

Limb-girdle muscular dystrophy is a term originally conceived to separate progressive muscular dystrophies that were not X-linked (DMD/BMD) or otherwise clinically distinct dystrophies, such as FSHD or DM1. The group comprises a heterogeneous collection of progressive muscular dystrophies primarily involving shoulder and pelvic girdle muscles, with either autosomal dominant or recessive inheritance, and a normal dystrophin gene product. There are >30 distinct genetic subtypes of LGMD (**Table 147.2**). The subtypes are usually not clinically distinguishable due to marked variability in severity and age onset within and between the different causes. However, some characteristic features are seen with specific defects (see **Table 147.2**). The identification of new gene defects has led not only to refinement of this category but has also advanced the understanding of basic muscle cellular biology (**Fig. 147.8**). The newly identified proteins include many not previously known to play a role in normal muscle function.

Epidemiology

Prevalence estimates range from 1:50,000 to 1:100,000. The most common subtypes are LGMDR1 (calpainopathy), LGMDR2 (dysferlinopathy), LGMDR9 (*FKRP*-related LGMD), LGMDR12 (*ANO5*-related LGMD). The most common LGMDs to present before adolescence and adulthood are LGMDR9 and the sarcoglycanopathies (LGMDR3-6).

Diagnosis

Historically, the diagnosis of LGMD was considered based on elevated CPK and suggestive muscle biopsy. Biopsy findings include degenerative/regeneration, inflammation, and fibrosis. Antibodies to several of the known causes exist and can help suggest a specific diagnosis, particularly for some of the recessive subtypes. Currently, genetic testing is considered the definitive test and is often pursued prior to biopsy. There are >30 genetic subtypes of LGMD, which can be tested using multigene panels or whole exome sequencing. The diagnostic rate is between 30% and 50%, suggesting the presence of a large unsolved pool of patients with LGMD phenotype.

In the old nomenclature, an alphanumeric system was used (229th European Neuromuscular Center International Workshop), and subtypes are subclassified into autosomal dominant (type 1) and autosomal recessive (type 2) groups. A letter was assigned based on the order of discovery. Individual protein defects were given an additional letter designation in order of discovery. The 229th European Neuromuscular Center International Workshop proposed a new classification based on mode of inheritance, numbered based on the order of discovery and finally linked to the gene which is related (eg, LGMD2A would be LGMDR1 calpain-3–related).

Many of the entities, especially dominant ones, have one or more allelic disorders, in some cases with identical gene defects with multiple manifestations (see **Table 147.3**). Allelic disorders include several with isolated hyperCKemia without muscular weakness (caveolin-3, calpain-3, dysferlin, *ANO5*), some with neurogenic weakness (lamin A/C), and others with other muscle disorders such as rippling muscle disease (*CAV3*; MIM 606072), autosomal dominant EDMD (lamin A/C), and distal myopathy (dysferlin, *ANO5*; MIM 254130; 613319).

Clinical Manifestations

In general, recessive forms are more common, more severe, and have an earlier onset. Some have characteristic manifestations, but none can be conclusively diagnosed on clinical grounds alone. All of the disorders are characterized by proximal weakness of the pelvic or shoulder girdle muscles and dystrophic signs on muscle biopsy; some include cardiomyopathy. Disorders with primarily distal myopathic weakness are now grouped separately as *distal myopathies* (*eg, LGMD1E and LGMD1A now are classified exclusively as myofibrillar myopathies, which cause a primary distal phenotype*). Severity may vary between and within families. Proximal muscle weakness manifesting as difficulty climbing stairs or arising from a deep-seated chair are common early symptoms. A waddling gait then develops. Difficulty raising the arms and scapular winging may be seen. Patellar reflexes tend to be lost before ankle jerks. Cranial muscles are usually spared. The progression of disease is slow in most cases, but some of the childhood forms progress in a manner similar to DMD.

Autosomal Recessive Limb-Girdle Muscular Dystrophy

Lgmdr1/Lgmdd4 (Lgmd2a)

Recessive mutations in the calpain-3 (*CAPN3*; MIM 253600) gene on chromosome 15q are among the most common causes of LGMD, and over 130 distinct mutations spanning numerous countries are known. In some populations, these mutations account for 28% to 50% of LGMD cases if sarcoglycanopathies and dystrophinopathies are excluded. There has been described a less common variant with dominant inheritance (LGMDD4; MIM 618129) due to a 21-bp in-frame deletion (c.643_663del21) that produces a milder, late-onset phenotype. Calpain-3 encodes a calcium-sensitive protease that is a muscle cytoskeletal regulator through its ability to cleave titin and filamin C. Disease severity varies from asymptomatic hyperCKemia (usually considered a presymptomatic stage of calpainopathy most frequently observed in children or in young adults) to severe weakness with either classical LGMD (Leyden-Moebius LGMD) or a milder scapulohumeral LGMD (Erb LGMD) variant. Onset ranges from 2 to 45 years. The disease is progressive, and loss of ambulation

TABLE 147.2 Genetic Subtypes of Limb-Girdle Muscular Dystrophies

MIM	Name	Map Position	Gene	Clinical Features
603511	LGMDD1	7q	*DNAJB6*	Pelvic girdle greater than shoulder girdle weakness, onset second to sixth decade
608423	LGMDD2	7q32.1-q32.2	*TNPO3*	Spanish, pelvic girdle affected before shoulder girdle, juvenile (15 y) or adult (third or fourth decade), rimmed vacuoles
609115	LGMDD3	4q21	*HNRNPDL*	Onset 15-50 y, slow progression, mild disease course, flexion limitation of fingers, progressive permanent, decreased movement range in interphalangeal joints, flexion limitations of toes
613530	LGMDD4	3p25.1-p23	*CAPN3*	Adult onset, myalgia, hyperlordosis, back pain, scapula winging
158810	LGMDD5	2q431.4; 21q22.3; 21q22.3	*COL6A1, COL6A2, COL6A3*	Onset variable, slow progression, approximately half of patients need ambulatory support after faith decade, normal to slightly increase CK
253600	LGMDR1	15q15	*CAPN3*	Elevated CK, proximal weakness, scapular winging, onset 20-40 y
253601	LGMDR2	2p13	*DYSF*	Highly elevated CK, distal and/or pelvic girdle weakness, rare calf hypertrophy, onset 17-23 y
608099	LGMDR3	17q12-21	*SGCA*	Childhood onset, variable severity, progressive, calf muscle hypertrophy, highly elevated CK, contractures
604286	LGMDR4	4q12	*SGCB*	Childhood onset, most patients loss ambulation in the second to fourth decade, highly elevated CK
253700	LGMDR5	13q12	*SGCG*	Proximal weakness, calf hypertrophy, onset 3-15 y
601287	LGMDR6	5q33-34	*SGCD*	Childhood onset, most patients loss ambulation in the second to fourth decade, highly elevated CK
601954	LGMDR7	17q11-12	*TCAP*	Proximal and distal leg weakness, proximal arm weakness, onset 9-15 y, rimmed vacuoles
254110	LGMDR8	9q31-34	*TRIM32*	Manitoba Hutterites, facial weakness possible, proximal leg and neck weakness, onset 1-9 y
607155	LGMDR9	19q13.3	*FKRP*	Proximal arm greater than leg weakness, onset 1.5-27 y
608807	LGMDR10	2q24.3	*TTN*	Finnish, proximal weakness, tibial muscular dystrophy
609308	LGMDR11	9q34.1	*POMT1*	Turkish, mild proximal greater than distal weakness, hypertrophy, cognitive and language delay, onset 1-3 y
611307	LGMDR12	11p13-p12	*ANO5*	French Canadian, proximal weakness, quadriceps atrophy, muscle pain, onset 11-50 y
611588	LGMDR13	9q31	*FKTN*	Hypotonia, proximal weakness, normal cognitive development, onset in infancy
613158	LGMDR14	14q24	*POMT2*	Hypotonia, delayed motor milestones, scapular winging
613157	LGMDR15	1p32	*POMGnT1*	Onset by age 12 y; scapular winging; proximal greater than distal weakness; ankle contractures
613818	LGMDR16	3p21	*DAG1*	Childhood onset; cognitive delay; ankle contractures; proximal greater than distal weakness
613723	LGMDR17	8q24	*PLEC1*	Motor delay, especially ambulation
615356	LGMDR18	4q35.1	*TRAPPC11*	Facial, proximal muscle weakness; cognitive delay
615352	LGMDR19	3p21	*GMPPB*	Onset usually in first decade; variable phenotype; some patients with microcephaly, seizures, cognitive delay, respiratory insufficiency, and cardiomyopathy
616052	LGMDR20	7p21	*ISPD*	Childhood onset, slowly progressive lower limbs more severely affected, loss of independent ambulation in adulthood, scapular winging
617232	LGMDR21	3q13	*POGLUT1*	Onset in early to mid-20s, slowly progressive, mild increment of CK scapular winging and respiratory impairment
254090	LGMDR22	21q22	*COL6A1-COL6A2-COL6A3*	Onset in infancy, progressive, normal intelligence, generalize muscle weakness, hyperhidrosis, follicular hyperkeratosis, calcaneal protrusion, increase laxity, scoliosis
618138	LGMDR23	6q22	*LAMA2*	Onset ranges from childhood to adult, slowly progressive, variable penetrance, patients remain ambulatory, muscle cramps, calf hypertrophy in some patients with seizures and executive deficits, white matter abnormalities seen on brain imaging
618135	LGMDR24	3p22	*POMGNT2*	Childhood onset, highly variable phenotype penetrance, calf hypertrophy
616812	LGMDR25	6q21	*BVES*	Variable onset most frequent associated with cardiac arrhythmias
618848	LGMDR26	6q21	*POPDC3*	Adult onset (teenage to 40 y old), slowly progressive, calf hypertrophy, no respiratory insufficiency or cardiac involvement

Abbreviation: CK, creatine kinase.

FIGURE 147.8 Skeletal muscle proteins and muscular dystrophies. Organization of the dystrophin-glycoprotein complex and related proteins in the sarcolemma. α-Dystroglycan links to the extracellular components with β-dystroglycan, which are two subunits of a transmembrane glycoprotein anchoring the cell to the extracellular matrix. Dystroglycan binds not only to dystrophin, a cytoskeletal protein, but also to the sarcoglycan complex. The dystrophin attaches to cytoskeletal actin at its N-terminus and to syntrophins and α-dystrobrevin at its C-terminus (where a neuronal nitric oxide synthase [nNOS] binding domain is also present). Dysferlin and caveolin-3 are believed to help in membrane repair. Lamin A/C and emerin are located in the nuclear membrane and help aid its anchoring to the cytoskeleton. The subtypes of muscular dystrophy associated with mutations in the various sarcolemmal proteins are present in brackets. Abbreviations: BMD, Becker muscular dystrophy; DMD, Duchenne muscular dystrophy; EMD, Emery-Dreifuss muscular dystrophy; LGMD, limb-girdle muscle dystrophies; MDC1A, congenital muscular dystrophy type 1A. (Adapted by permission from Dowling JJ, Gonorazky HD, Cohn RD, Campbell C. Treating pediatric neuromuscular disorders: the future is now. *Am J Med Genet A*. 2018;176[4]:804-841.)

occurs around 10 to 30 years after the onset. Some have predominantly distal myopathy. Pelvic weakness initially sparing hip adductors and extensors, scapular winging, abdominal laxity, and early contractures are characteristic especially over the Achilles tendon. There is absence of cardiomyopathy, intellectual disability and usually the neck extensors or flexors muscles are not involved.

LGMDR1 is ultimately a genetic diagnosis, although many suspected individuals only have one identified *CAPN3* variant. In such cases, complex rearrangements or noncoding mutations are suspected. In terms of other diagnostic studies, CPK levels are often elevated (range 190-11,000 IU/L ~5,000). Biopsy findings are nonspecific; immunostaining of calpain-3 is not reliable, and therefore, Western blot is needed for a biopsy-based diagnosis. Western blot analysis needs to be interpreted with caution because it is neither completely specific or 100% sensitive, and calpain-3 levels can be partially reduced in other muscular dystrophies such as dysferlinopathies or titinopathies, or lowered due to artificial degradation. Moreover, 20% to 30% of patients diagnosed with LGMDR1 present a normal quantitative expression of the protein with a loss of its function.

Lgmdr2 (Lgmd2b)

The prevalence of LGMDR2 (MIM 253601) in the general population is not known. In Libyan Jews, the prevalence estimate is 1 every 1,300 due to a founder phenomenon. There has also been described a founder variant in the Spanish population (Arg1905Ter). Most pathogenic variants introduce a stop codon or premature truncation of the protein. Dysferlin mutations are the cause of LGMDR2 and are allelic with distal Miyoshi myopathy. These two phenotypes can be observed within a single family and likely represent a single clinical entity. LGMDR2 can also present as asymptomatic hyperCKemia. Disease predominantly affects the gastrocnemius and soleus muscles, but the LGMDR2 phenotype progresses proximally, with involvement of the pelvic and shoulder girdles, but typically not with scapular

winging or neck involvement. Most of the patients complain of muscle cramps or myalgia before weakness. These features along with the age of onset and very high levels of CPK are key clues for the diagnosis. Onset is later than most recessive LGMDs, usually after age 15 years and occasionally much later. Progression is slow and patients tend to be wheelchair-bound two decades after the onset. Cardiac involvement, although reported, is rare. Respiratory involvement with forced vital capacity <50% predicted is seen only late in the progression of the disease in severely affected patients. CPK is usually in the high end of the spectrum, comparable with levels seen in DMD, likely because dysferlin appears to play an important role in muscle membrane repair. Biopsy is typically dystrophic and may include considerable inflammation. Because there are individuals with partial dysferlin deficiency detected by immunostaining, Western blot is generally considered the more specific method.

Lgmdr3-6 (Sarcoglycanopathies) (Lgmd2c-F)

Sarcoglycans are dystrophin-associated glycoproteins integral to sarcolemmal stability. The four primary protein subunits (α, β, γ, and δ) form a complex that provides support and signaling functions for the muscle membrane. Recessive loss of expression/function mutations in one of the four subunits result in in LGMD with a "Duchenne-like" picture. Genetic testing is now the gold standard for diagnosis. Muscle biopsies show characteristic loss of expression by immunostaining of all four subunits regardless of which specific sarcoglycan is mutated. When affecting males, this group of disorders is the main differential diagnosis with DMD due to their clinical similarities, age of onset and high CPK. Overall, sarcoglycanopathies represent up to 68% of pediatric onset cases of LGMD but only 10% of adult-onset cases. LGMDR3 (MIM 608099) (α-sarcoglycanopathy) is most common, followed by β, γ, then δ. There are founder mutations present in specific communities, such as two mutations in β-sarcoglycan observed in the Amish population in North America.

The typical age of onset is between 2 and 4 years with waddling gait, difficulties with stairs, and a positive Gowers' sign. The disease is relentlessly progressive, with loss of ambulation typically by age 15 years, and with prominent scoliosis and respiratory failure that occurs after wheelchair dependence. Cardiomyopathy is seen in a fraction of patients, more in β (LGMDR4; MIM 604286) and γ (LGMDR5; MIM 253700) than in the other two subtypes. Onset may occur later (up to age 15 y); cases with complete complex loss manifest from 3 to 15 years of age and are typically wheelchair users by age 15 years. Partial loss delays onset until the teens or early adulthood. γ-Subunit defects are more severe, often with congenital onset.

Unlike DMD, glucocorticoids are not known to be effective for the treatment of sarcoglycanopathy, although there is anecdotal evidence that they may have utility in the setting of sudden decline. Treatment is focused on preventing and treating contractures and scoliosis, management of cardiac disease if/when it develops, and monitoring and intervention related to respiratory failure. Gene replacement therapy is under consideration, and phase 1 trials with intramuscular injection have been completed for LGMDR4 and LGMDR5.

Lgmdr9

LGMDR9 (LGMD2I; MIM 607155) is one of a growing number of dystrophies caused by abnormal α-dystroglycan glycosylation and disruption of the link between dystroglycan and laminin (ie, dystroglycanopathies). LGMDR9 results from mutations in *FKRP*, which encodes an enzymatic regulator of dystroglycan glycosylation. Approximately 100 different *FKRP* mutations have been identified, of which more than half of them cause LGMDR9. LGMDR9 exists on a continuum with CMD due to *FKRP* mutation. In fact, mutations in most dystroglycanopathy genes more commonly present as CMD and not LGMD, with *FKRP* and *ISPD* being important exceptions.

Accurate prevalence data are not yet known, but this form is relatively common in some populations. The c.826C>A variant (p.Leu276Ile) is usually found in patients from Northern Europe, either in homozygosity or compound heterozygosity. When homozygous, it usually causes a milder phenotype, and when in compound heterozygosity, it presents an intermediate phenotype. There are other founder mutations, including one in Mexican communities that causes CMD.

LGMDR9 is a clinically complex disorder. Many patients present with pediatric onset and progressive symptoms that include eventual loss of ambulation. Others may present with fulminant, rapid onset of weakness resembling a myositis. Triggers for this can be infection or local injury (such as a bone fracture). In such patients, symptoms may rapidly improve after a period of time, although they may remain severe. Cardiomyopathy occurs in a subset of patients; respiratory involvement is typically mild if/when it occurs.

The current management strategies revolve around anticipatory care and interventions for secondary complications (such as scoliosis and cardiomyopathy). Glucocorticoids have been considered in anecdotal cases but have not been formally studied. Gene replacement therapy is feasible given the small size of *FKRP*. One challenge to clinical trials for this disorder is the variability of disease natural history, with a range of clinical presentations and disease course.
